The most important adverse finding on admission to the trial is exercise non compliance Total drop-outs have a risk of recurrence more than 20 times the average and limited exercise participation also increases risk by a factor of at least five Is this because advanced disease *and* poor myocardial function keeps some patients from performing the prescribed exercise? Residual disability shortness of breath and angina all increase the chances of recurrence but *nevertheless cardiac* problems are rarely cited as a reason for non compliance It is possible that those who fail to exercise are missing a therapeutic benefit of vigorous exercise but this again is doubtful since the figures from Southern Ontario and other trials to date suggest no advantage of high intensity exercise relative to *homeopathic* recreation or inactivity The most probable explanation is that exercise non compliance is serving as a marker of a generally adverse life style Many studies have shown the linkage between poor exercise compliance persistent smoking and obesity Rechnitzer and colleagues (unpublished *data*) *have* also noted that a combination of Type B personality a blue-collar job and vigorous exercise yield a poor prognosis Finally the group with recurrent infarction shows an above-average proportion of subjects engaged in commerce with a deficit in professional and managerial work.

Signs of a poor prognosis include cardiac enlargement aneurysm polyfocal ventricular premature beats exercise ST segmental depression and a serum cholesterol > 270 mg dl *The importance of deteriorating myocardial function is al*

From Stewart, I McD G., Lancet 33 861 1979 Reproduced with permission.

F D P s ≤ 90 mm Hg the pressure falls were all markedly greater than in unaffected controls matched for C H D risk factors that included form of treatment age sex and established pretreatment diastolic pressure

These findings suggest that in severe middle aged hypertensive subjects attempts at normalization of the pressure may precipitate as many infarctions as it prevents perhaps cancelling out a lessened incidence at high levels a concept that is supported by an acknowledgment from Berglund and colleagues that in their study on the effects of treatment the percentage of well controlled patients after 2 years treatment was indeed low despite their lessened infarction rate compared with that of the untreated

All this constitutes a challenge to the popular concept of good control. But it can scarcely be accounted surprising Misled by mean values and persuaded by those who would have it that hypertension is a potent cause of coronary atheroma clinicians throughout the world have continued to pay lip service to the proposition that reduction of blood pressure to normal levels should diminish the incidence of myocardial infarction in hypertensive patients Yet there is no convincing evidence that hypertension significantly favors coronary atherogenesis nor that lowering systemic pressure can arrest it Certainly the prospect of longevity as shown by actuarial tables is improved by a blood pressure that has continued or possibly (as remains to be seen) has always been controlled at a normal level But this simple epidemiological appreciation takes no account either of the individual patient or of the site of the fatal lesion Some 30% of middle aged Englishmen and no doubt many more such men who have adopted the life styles of the Western type civilization whether hypertensi e or not already have advanced coronary artery disease often unsuspected[ ] It is easy to believe that severe contrived reductions in their systemic arterial pressure impinging fortuitously upon the constantly changing mechanisms of auto-regulation may sometimes lead to disastrous failures of coronary perfusion, perhaps with stasis and platelet aggregation the risk made all the greater by the diverse and frequently unpredictable modes of action of the hypotensive drugs concerned. Such combinations of drug and circumstance have already been shown to precipitate myocardial infarction in patients under close observation in hospital

For many reasons the clinical reduction of blood pressure is an imprecise exercise Even when aimed at levels well above normality " it may still occasionally overshoot the mark to a degree that threatens critical and possibly fatal, myocardial ischaemia Thus it may well be that in its treatment no less than in its natural history hypertension presents a dual threat of infarction and sudden cardiac death by precipitation of these events at each extremity of the pressure scale This threat should be avoidable in both its forms if "good control" be taken to imply not normality the standardized average for age and sex but a decrease in pressure sufficient to restrain hypertensive injury to target organs, including the heart while avoiding such hypotension as may set off infarction.

In 1957 it was suggested that "even a limited depression of the blood pressure could be as effective "as the most exacting control. " Today it would seem reasonable to conclude that at least in severe hypertensive subjects the policy should be one of reduction into an optimum range calculated as far as possible for the individual that is likely still to be considerably above that of normalization" after induced pressure falls of perhaps no more than about 22% or to a diastolic pressure of around 104 to 110 mm. Exercise and recurrence of myocardial infarction

The hypothesis that vigorous exercise rehabilitation is of benefit to patients following myocardial infarction is currently being tested in Southern Ontario using a stratified randomized controlled trial To date 50 of the 751 patients have been followed to the point of reinfarction and the resultant data has now been analyzed seeking clues to those individuals with an above average risk of a further coronary event

The most striking feature of this survey is the similarity of patients who infarct and those who do not[1] While the Southern Ontario multicenter sample included some individuals who had a slow progressive extension of their disease in many individuals the second infarction (like the first) occurred with little clinical or physiological warning This may reflect the nature of patients referred for exercise rehabilitation all were by selection under 54 years of age while the exercise program may have attracted cases with a relatively mild initial episode and/or a fairly complete restoration of myocardial function

The only clinical clue to the likelihood of reinfarction gained from the patient s initial records was a history of multiple infarctions Characteristics of the initial attack (symptomatology ECG changes enzyme changes cardiac arrest dysrhythmia and minimum systolic blood pressure) did not modify subsequent prognosis Presumably residual myocardial function is more crucial than the characteristics of the previous acute episode The referral process and criteria of admission to the multicenter trial may also have sorted o relatively uniform type of patient suited to exercise wit infarct of less than average severity

The most important adverse finding on admission to trial is exercise non compliance [2] Total drop-outs hav risk of recurrence more than 20 times the avera e limited exercise participation also increases risk by a facto at least five Is this because advanced disease and p myocardial function keeps some patients from performing prescribed exercise? Residual disability shortness of bre and angina all increase the chances of recurrence nevertheless cardiac problems are rarely cited as a reason non-compliance [3] It is possible that those who fail to exer are missing a therapeutic benefit of vigorous exercise but again is doubtful since the figures from Southern Onta and other trials to date suggest no advantage of h intensity exercise relative to homeopathic recreation or u tivity The most probable explanation is that exercise n compliance is serving as a "marker of a g nerally adv life-style Many studies have shown the linkage between p exercise compliance persistent smoking and obesity Rechnitzer and colleagues (unpublished data) have also no that a combination of "Type B" personality a blue-collar, and vigorous exercise yield a poor prognosis Finally the gr with recurrent infarction shows an above average proport of subjects engaged in commerce, with a deficit in professional and managerial work.

Signs of a poor prognosis include cardiac enlargemen aneurysm polyfocal ventricular premature beats, exercise T segmental depression and a serum cholesterol > ? 0 mg d The importance of deteriorating myocardial function is also

ested by the inability to develop a normal rise of systolic blood pressure during exercise. Nevertheless, physiological response to exercise does not show major differences in those who sustain reinfarction. Possible warnings include a low cardiac output relative to work rate, a widened arteriovenous oxygen difference, and poor matching of ventilation and perfusion. None of these indicators are very clear-cut, presumably because recurrent disease includes both cases of sudden ventricular dysrhythmia and individuals who develop progressive pump failure.

With the possible exception of exercise non-compliance, the ratios for the various warnings we have discussed are too low to be of great value in advising individual patients. The safety of exercise rehabilitation will thus continue to depend upon a cautious initial prescription of exercise, gradual progression, and temporary restriction of activity in the face of adverse symptoms.

Giant cell arteritis—a cardiological blind spot?

Few would disagree that the cardiologist has been faced with and has overcome several major challenges in his field during recent decades. One which remains and unfortunately appears to have been largely ignored is that presented by giant cell arteritis (GCA). Thus Paulley recently asked the question: "What, then, is happening to the bulk of these patients referred to cardiologists who, it seems, are either seeing this disorder and not diagnosing it or diagnosing it but not reporting it?" Our clinical experience, a survey of publications, and the lack of reference to GCA in major cardiological texts all suggest that the former situation is more prevalent. Indeed, with GCA, diagnostic delays or failures permeate well beyond the boundaries of cardiological practice and undoubtedly occur more frequently than is generally appreciated within every major subspecialty of internal medicine.

Although GCA may cause angina pectoris, myocardial infarction, aortic regurgitation, aortic dissection, congestive cardiac failure, perhaps pericarditis, and even simulate infective endocarditis, its prevalence in cardiological practice is unknown. Recognition that arteritis may be the underlying cause of these cardiac events during life is by no means easy, demanding a high index of suspicion and awareness of the deceptive natural history of the disease. Yet there are data indicating that GCA is by no means a rare disease, affecting more than one per cent of the elderly Caucasian population. The dominance, however, of atherosclerosis in the league of diseases in Western countries has generated complacency with regard to consideration of less commonly seen disorders such as this arteritis.

It has become increasingly apparent that GCA is a chronic disease of varying severity and fluctuating course extending over a few to as many as 10 to 15 years. While temporal arteritis is easily diagnosed, events such as unexplained anemia, pyrexia of undetermined origin, malaise, depression, or a negative laparotomy for possible malignancy, any of which may have occurred months or years earlier, are presentations to which the cardiological mind is not often attuned. Nevertheless, these may be the only clues indicating the true cause

Effective coronary care and mortality rates

To the Editor

May I refer to your Editorial Home or hospital for myocardial infarction—who cares? This is based on the Nottingham study reported in 1978 I would like to point out the limitations of this study It was carried out over a four year period and covered a population of approximately 100 000 From the expected incidence of myocardial infarction some 1,200 cases would have been anticipated among that population over the four year period Two hundred and sixty four patients suspected of having a myocardial infarction were randomized However only 150 of these had a definite or probable myocardial infarction and were randomized to home or hospital treatment Thus of the patients likely to have had a myocardial infarction only 12 5% were randomized This is remarkable in that the Nottingham workers point out that one of the major defects of the Bristol study was the small proportion of patients who were randomized

From their study the Nottingham workers concluded that "For the majority of patients to whom a general practitioner is called because of suspected infarction hospital admission confers no clear advantage " Yet in their study over 40% of the patients with suspected myocardial infarction had contacted their doctor within one hour of the onset of symptoms and nearly 60% within two hours Nevertheless the average time from the onset of symptoms to the mobile team s arrival with the patient was three hours and a further two hours elapsed prior to randomization It may be concluded that in the Nottingham study there was a larger administrative delay than patient delay The authors record that during the time between the patient s call for help and the arrival of the mobile team 14 patients died presumably suddenly and from ventricular fibrillation A further seven patients developed ventricular fibrillation after arrival of the team yet only three of these seven survived six weeks Seventy three percent of the patients managed by the Belfast unit who developed ventricular fibrillation outside hospital after the mobile team s arrival survived to leave hospital The standard of coronary care received by the patients in Nottingham both outside and inside hospital must be questioned since it is reported that patients on admission to the coronary care unit come under the care of a general physician on duty that day The head of the unit considers his role to be that of an administrator and educator The junior doctors manning the mobile coronary care unit are drawn from the general medical units of the hospital

In the Editorial the authors state that "76% of patients seen by the team were suitable for care at home Yet among those patients with a final diagnosis of definite or probable myocardial infarction who were excluded from randomization the six week mortality rate was 37% No explanation for this very high mortality rate is given

The Nottingham data show the obvious If patients are seen late after the onset of symptoms the effect of coronary care will be minimal Despite the evidence from Belfast and Seattle Hampton and Nicholas conclude that mobile coronary care units as at present envisaged will not appreciably affect mortality from heart attacks This conclusi n dangerously erroneous and has already inhibited the develo ment of prehospital coronary care schemes in Britain sin apparently the policy of the Department of Health is based the Nottingham propaganda Sadly therefore there will co tinue to be 5 000 unnecessary deaths annually in the Unit Kingdom

Of senile anemia

Old patients with or without active heart disease regularly with chronic anemia It is important that the general health of the patient with heart disease always be considered not only because associated diseases contribute to the patient s symptom complex but also because some associated diseases affect the heart directly and/or indirectly This is certainly true of anemia When the concentration of red cells and hemoglobin is low the oxygen transport buffer mechanisms, and other important functions of hemoglobin and erythrocytes are impaired and the myocardium suffers as a consequence

Heart disease is especially common in older people It is well to realize that many old people have chronic anemia for which the etiology remains unknown Even after extensive hematologic study with all available methods the cause is not established satisfactorily The anemia may vary from mild to severe Yet the use of all therapeutic measures and agents fails to modify it except for the temporary influence of transfusions. But transfusions can be dangerous in that they may precipitate congestive heart failure in people with heart disease when transfusions are not used properly and cautiously

This type of chronic anemia of "unknown" cause in old people may be called senile anemia " the anemia of old age the result of poor function of an old hemopoietic system Unless the anemia is severe and is contributing to the ill health or to the cardiac disease of the elderly patient it should be left alone After all, sluggish and relatively inactive old people do not need as much circulating blood or hemoglobin as young extremely active people do

Sex and the differential diagnosis of uncomplicated angina pectoris

To the Editor

In a recent publication from a widely respected epidemiological investigational team on the occasion of reporting an extraordinary high percentage of remission of angina pectoris cases first the validity of the acquisition of the anginal symptomatology was questioned and secondly a disturbing distribution between sexes of such patients emerged

The aim of this paper is not to deal either with the remission rate of this symptom complex or with its eventual significance The finding however of a 13% preponderance of women (N = 84) over men (N = 74) in a natural (unselected) population is in fact astounding and not only on theoretical, but also on practical grounds. It was therefore thought to be very constructive to expose briefly the findings of an investigation concerning this matter We evaluated with the HIP questionnaire for angina pectoris 200 consecutive cases addressed to us with the problem or recurring chest pain The following groups of cases were not included in the above 200 cases (1) cases with historical and or electrocardiographic documentation of old myocardial infarction (2) cases where the electrocardiographic and or enzymatic follow up was diagnostic of a re ent myocardial infarction (3) cases with valvular disease click syndrome cardiomyopathies (4) cases with bundle branch [illegible] k and (5) cases of recent administration of digitalis prep ration (The last two prerequisites were set because of a parallel study of the resting repolarizatio[illegible] the included cases)

Thus the consecutive studied cases consisted of 108 men 92 women The characterization of the chest pain compl[illegible] by the HIP questionnaire and other relevant parameters shown in Table I.

It can be seen from the table that the mean a e—as expected—was higher in cases with angina pectoris as [illegible] pared with cases of non anginal chest pain (and significa[illegible] so for men $p < 0\,01$) also SBP was higher in the same co[illegible] (and significantly so for women $p < 0\,05$) It is interesting to note the high occurrence of abnormal resting repolarization in cases with non anginal chest pain although it will not be discussed here The most important finding however was that the probability of a middle a ed person presenting with recurring chest pain to have angina pectoris is 0 38 (41 out of 108) for men and only 0 03 (3 out of 9?) for women Therefore angina pectoris is almost 12 times less frequent in women than in men of comparable a e This conclusion is in absolute contrast to the above mentioned findings (from the Framingham study)

It would be fruitful to speculat about this striking differ ence The whole evidence so far has been for a clear predom nance of male sex in Heberden s classical description of [illegible] cases of angina pectoris only three women were encountered In seven series on the subject (published between 19[illegible]0 a[illegible] 1959) and reviewed by Segal the ratio varied between ? 5 and seven men for one woman

Burch stated that angina pectoris was more common in men than in women Finally Friedberg mentioned a ratio of three to six men for each woman

One might argue that in an unselected population (such as that of the Framingham study) the distribution of angina pectoris could be different from cases which consult physicians This hypothesis is very unlikely especially in view of the very divergent proportions On the other hand, one may question the validity of history taking In fact, in the above mentioned study from Framingham for the purpose of explaining the striking frequency of the remission rate of angina pectoris the authors discussed the possibility of faulty interpretation of the angina symptom complex For the rejection of this possibility they argued that the veracity of the clinical conclusion could not be judged against laboratory evidence (including coronary arteriography) because angina pectoris is by definition the evaluation of the symptomato[illegible] only And although this argument is sound it does not preclude us from questioning the best manner of acquiring and evaluating the historical information Proudfit and associates commented upon the faulty first impression about the diagno-

itral valve prolapse syndrome

o the Editor:

In the March 1979 issue of AMERICAN HEART JOURNAL here appeared several interesting articles about the mitral alve prolapse syndrome. In the study by Udoshi and associates (97:303, 1979) the authors made some interesting bservations regarding time relations between systolic murmur and echocardiographic mitral prolapse. Although the tudy was not primarily designed to evaluate the acoustic haracteristics of the mitral valve prolapse syndrome, I should ike to make some comments regarding these characteristics.

In typical cases the murmur associated with mitral valve rolapse is meso- to telesystolic and there is correlation with he timing of prolapse on echocardiography. On the other and, there are cases of mitral valve prolapse where we can register only early systolic murmurs, but now they do not correspond with the timing of prolapse determined by echocardiography. Of six patients with protosystolic murmur described in the article by Udoshi and colleagues, five had late systolic prolapse and one had holosystolic prolapse.

In those patients with early systolic murmur and late systolic prolapse there need not be any causal relationship between the mitral valve prolapse and the murmur. The latter may represent coincidental murmur of different genesis, for instance an innocent murmur. In such cases the mitral valve prolapse in reality is silent. Perhaps the mitral valve prolapse syndrome only rarely or never causes early systolic murmurs.

There are some practical implications of this presumption. Subjects with systolic murmur which *is related* to the mitral valve prolapse generally have a less favorable prognosis regarding progression of mitral regurgitation or the risk of developing infective endocarditis, when we compare them with those patients who have only an isolated systolic click. Hence in subjects with the mitral valve prolapse syndrome and protosystolic murmur with or without an associated systolic click, the mere existence of the murmur perhaps does not influence the prognosis.

Spontaneous resumption of sinus rhythm after prolonged AF

To the Editor:

In the Case Report of spontaneous resumption of sinus rhythm in an elderly patient after 13 years of permanent atrial fibrillation, Dr. Chevalier (AM HEART J 98:361, 1979) describes a case showing an interesting and a rare event. We had a similar experience with two patients (R I Med J 325, 297 June 1977) who, on recent follow-up visits, have been noted to maintain normal sinus rhythm. As noted also by Dr. Chevalier, we believe that Holzmann's theory offers the best explanation for this phenomenon. We postulated the following. Atrial fibrillation is usually explained on the basis of two mechanisms—i.e., the unifocal theory and the reentry phenomenon (or the circus movement). It is possible that progressive fibrotic changes taking place in the atria may abolish atrial fibrillation. In the case of unifocal theory, the triggering focus may be eradicated as it gets incorporated into the fibrotic process. In the case of the reentry phenomenon, it is possible that the fibrotic process interrupts the reentry pathway and terminates atrial fibrillation. In any case, it is necessary that the sinus node be capable of taking over once atrial fibrillation ceases. If this was not the case, sinus arrest would result on cessation of atrial fibrillation, as was seen in the case described by Reeve and colleagues (AM HEART J 90:127, 1975). Thus the change from chronic atrial fibrillation to spontaneous sinus rhythm probably represents worsening of the conduction system.

Adsorption of NTG

To the Editor:

We agree with Cacace and associates that adsorption of nitroglycerin to glass containers does not create many problems; our own results concerning this item are consistent with their findings. However, the clinical importance is doubtful when you don't know how much NTG is retained in the infusion system. Therefore we conducted an infusion set adsorption study.

NTG solutions were prepared from an ethanolic stock solution containing 1% w/w of NTG by diluting with distilled water to a concentration of 5 mg/ml. The solution was filtered through an 0.2 micron filter and after discarding the first 50 ml. (we found up to 25% decrease of NTG after filtering the first portion) was filled into 5 ml. glass ampules. After sealing, the ampules were heated for 30 minutes at 105 (Branje and Berghuis[1])

Five milliliters NTG was added to 500 ml. of normal saline in a glass bottle and a polyvinyl chloride (pvc) infusion system was connected. Flow rate was kept constant with an Ivac 531 flow controller. Flow rates used were 0.25, 0.50, 0.75, and 1.00 ml./minute (equivalent to 12.5, 25, 37.5 and 50 micrograms per minute, respectively). Samples were retained at zero, 30, 60, 90, 120, 180, 240, 300, and 360 minutes and were immediately assayed by means of the kinetic method of Yap and coworkers. At the same time, samples drawn from the glass container were assayed; this concentration did not change during the experiment.

The results are summarized in Table I. The loss of NTG turns out to be flow-dependent; after a rapid decrease a gradual increase is subsequently seen which perhaps results in a plateau after six hours. For the fastest flow rate this seems to be at 90% of the original concentration, whereas it is only 60% for the lowest.

Most reports concerning the use of NTG infusions don't mention the type of infusion set they use. Our results indicate that this omission is not justified. Much time is spent on determining stability of intravenous fluids in bottles or bags,

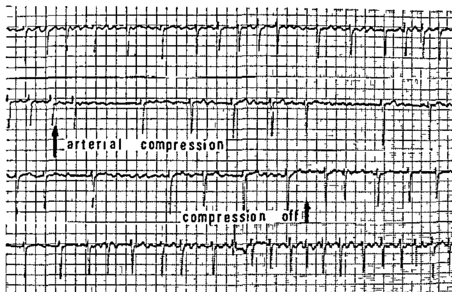

Fig 1 Continuous rhythm strip of a 45 year old woman with multiple A V fistulae in the left thigh. Upon compression of the left femoral artery the ventricular rate slows markedly from approximately 125 beats per minute to approximately 60 beats per minute with resumption of the previous rapid rate when the compression is released

additional example illustrating the great degree to which the atrioventricular node is under the control of the autonomic nervous system

Possible association of pneumonitis with amiodarone therapy

To the Editor

Amiodarone hydrochloride (Cordarone) is an effective agent in the treatment of various arrhythmias We would like to give a brief report on a patient with pneumonitis possibly related to the administration of this drug

A 50 year old male who had suffered myocardial infarction and ventricular tachyarrhythmias received amiodarone 400 mg per day One month later he started to complain of fatigue tachypnea at rest and dyspnea on exertion On examination there were decreased breath sounds but no wheezing or rales The chest roentgenogram showed diffuse interstitial and intra alveolar shadows which were indistinguishable from pulmonary venous congestion (Fig 1) Despite diuretic and digitalis therapy his condition deteriorate matically Pulmonary function tests demonstrated a r tive defect (FVC = 1 95 liters 46% of predicted value severe impairment of gas transfer (pO = 46 mm. pCO = 36 mm Hg) Hemodynamic studies excluded c failure (CI = 3 0 L/min/M PCWP = 2 mm Hg) demonstrated increased pulmonary arteriolar resistanc dyne sec/cm) and increased pressure in the pulm artery (46/16 mm Hg) and right ventricle (46/0 mm H the absence of another apparent cause an adverse react amiodarone was suspected and the drug was disconti Prednisone 60 mg/day was started and the patient's c tion improved rapidly The chest roentgenogram sh complete resolution of the infiltrates (Fig 1) and the pu nary function tests returned to normal

Several factors indicate that the pulmonary manifest and clinical symptoms seen in this patient may be attri to amiodarone First there was a normal base line of pu nary functions before the administration of this drug se there was a latent period between the initiation of therap the onset of illness third amiodarone was the only drug taken by the patient Cessation of this agent and s therapy resulted in a prompt normalization of the cl picture radiologic changes and functional abnormalities chest roentgenogram and pulmonary function tests are patible with hypersensitivity pneumonitis

of angina pectoris, and Welch and co-workers underlined the frequent non-concordance between the history of angina pectoris in women and their findings on the coronarogram.

The superiority of the HIP questionnaire[4] used by us compared to the more conventional one used in the Framingham study lies in the fact that it accounts for not only the positive indicators to the angina symptom complex but also for its negative indicators thus permitting a more balanced evaluation of the chest complaint in a given person. The fact that in women uncomplicated angina pectoris is much more infrequent than in men and even in these women the history of angina pectoris is an insecure predictor of coronary artery disease is corroborated also by elegant correlations with coronarographic and anatomical findings.

In conclusion in reality not only do men far outnumber women for uncomplicated angina pectoris but also the diagnosis of typical angina pectoris in a woman complaining of chest pain is, in the light of our findings very questionable from the beginning and only a very meticulous systematic search and with cross matching history taking can secure a valid conclusion.

Branham's sign with atrial fibrillation

To the Editor

In 1890 Branham described the transient slowing of the heart rate which occurs during manual compression of an arteriovenous fistula. We recently encountered a patient who demonstrated Branham's sign in the presence of atrial fibrillation. In surveying the literature and the many hundreds of patients described therein with arteriovenous fistula we were unable to find a case of Branham's sign during atrial fibrillation. Our patient was a 45-year-old female with multiple arteriovenous communications in her left thigh, who had developed congestive heart failure as a result. She had a rapid irregular heart rate of 170 to 130 per minute. Upon manual compression of the femoral artery there was a dramatic and almost instantaneous slowing of the heart rate to approximately 60 beats per minute with an immediate resumption of the rapid rate as soon as the compression was terminated (see Fig. 1).

The mechanism of the phenomenon in atrial fibrillation is undoubtedly the same as in patients with sinus rhythm, namely a reflex response due principally to the increase in blood pressure and the decrease in venous filling. The difference lies in the fact that whereas the exquisite control of heart rate by the automatic nervous system is usually exercised via effects upon the *sinoatrial* node in the patient with atrial fibrillation control is via the *atrioventricular* node. Branham's sign in the presence of atrial fibrillation provides an

Book reviews

Cardiovascular Review By Gerald C Timmis M D Baltimore 1979 The Williams & Wilkins Company 227 pages Price $10 9ɔ

This is a review of the highlights of reports that appeared in American cardiovascular journals for the past 7 years This brief review of selected papers include such a pects of heart diseases as ischemic heart disease valvular heart disease arrhythmias conduction defects effects of therapy and drugs acromegaly amyloidosis asymmetric septal hypertrophy athletic heart cardiomyopathy and others The review is remarkably thorough and extensive for a book of only 227 pages The review like annual reviews in other fields, is useful to many readers but unlike the annual reviews this one includes selected publications over the past 7 years Each statement is well documented to facilitate a more extensive consideration of aspects of cardiovascular problems that might interest the reader As with most reviews of this type this review presents the conclusions and recommendations of the authors of publications without critical analysis of the respective studies

Venous Thromboembolism Prevention and Treatment Edited by John L Madden M D and Michael Hume M D New York 1976 Appleton Century Crofts Inc 240 pages

This small succinct book of 240 pages is concerned with an important problem involving all branches of medicine All physicians are constantly concerned about thromboembolism in all seriously ill patients The many contributors have reviewed the problems effectively and briefly for all physicians The chapters include discussions of risk factors prevention early detection of venous thrombosis pulmonary embolism hemodynamic phenomena diagnosis use of the pneumatic venous pump and prophylaxis Each chapter is appended with a good selection of references The illustrations are good This is a good and useful single source on an important clinical state The papers were presented at a symposium in 1976 in New York City

Hypertension Determinants Complications & Intervention Edited by Gaddo Onesti and Christian R Klimt New York 1979 Grune & Stratton Inc 462 pages Price $39 50

This is the Fifth Hahnemann International Symposium on Hypertension an important and common illness of man The many presentations are grouped into five parts namely determinants complications end organ damage benefit and risk of intervention and therapeutic and preventive trials and community programs It is impossible in a brief review to consider each of the many presentations adequately In general the presentations are good and the discussions up to date The book should interest internists and general practitioners The book fails to date clearly the time of the symposium The great number of publications and symposia on hypertension in recent years makes it unavoidable to repeat what has been said many times and therefore each adds little new to the field Let us hope the next symposium will be limited to only what is new since this fifth one

The Treatment of Acute Myocardial Ischemia An Integrated Medical/Surgical Approach Edited by Lawrence H Cohn M.D., Mount Kιʌo N Y 19˜9 Futura Publishing Company 230 pages Price $23 00

This book by a urgeon of the Peter Bent Brigham Hospital along with contributors from the same hospital representing cardiology in medicine and pathology describes their prac employed in the management of ischemic heart di particularly acute myocardial infarction The book is brief lucid with the emphasis being on integration of the med and surgical specialties The eight chapters include the pat ogy of myocardial infarction pathophysiology surgical t nique and policies for emergency revascularization man ment of unstable angina acute infarction arrhythmias, mechanical complications The principles and pract described seem to be similar to those of other large clir groups found elsewhere in America This book, there outlines very well the practices at the Brigham

Histopathology of Cardiac Arrhythmias By Dr L R Milan 1978 Casa Editrice Ambrosiana 299 pages

This is the second edition on histopathology of car arrhythmias an important publication in cardiology The a tendency to fail to relate the structural changes in myocardium and conduction tissues to function when me ing patients with heart disea_e This book reveals very wel structural changes associated with heart disease Unfo nately the functional state is not necessarily relate explained only by anatomic changes Nevertheless, this l does indicate the pos.ible relationships of structure to f tion both in health and disease The author a patholog t performed an excellent service to cardiology in his studi this publication Rossi has clearly discussed and illustr extremely well the histology of the normal conduction t and morphologic alterations associated with cardiac di along with disturbances in the heart beat The photom graphs are very good and well selected This book shoul studied by all cardiologists It is highly recommended eve pathologists and anatomists

Heart Failure Edited by Alfred P Fishman New York 1 McGraw Hill Book Company Inc 356 pa es

This book contains the presentation on congestive h failure held in honor of Dr Isaac Starr of the Universit Pennsylvania There were many contributors from m parts of the U S A The presentations were concerned basic aspects of myocardial contraction direct assessmen cardiac contraction indirect assessment of cardiac perf ance consequences of heart failure and therapy of h failure Each presentation reflects the opinions and cons ations of the authors The papers are brief and the illu tions and text clearly presented As is true to a great exter present the accuracy of the measurements are not critic discussed and instrumentation is prominent in the prese tions Because recordings are obtained their usefulness is convincing in the understanding of CHF The literature is completely represented A reader who is interested in opinions of the various contributors to the symposium find them clearly expressed in their respective reports.

This reviewer would like to take this opportunity to exp his admiration for Dr Isaac Starr a fine man known for meticulous research and dedication to medicine and who ship Dr Fishman and the steering committee ha e don worthy and admirable job in planning and conducting th symposium With best wishes to Dr Starr an outstandi clinical investigator

Circulatory System Dynamics Edited by Abraham Noordergraaf New York San Francisco and London 19 8 Academ Press, Inc. 3ɔ1 pages Price $36 00

This is a very good review of the important procedures employed in medicine and physiology which relates the role of bioengineering to the study of normal and abnormal circulatory function The author included reviews of the circulatory system blood flow measurements arteries veins, microcirculation and the heart Anyone seriously involved in cardiology should find the book extremely interesting. The author does not exhaust the subjects selected for his ten chapters nor does he include a careful review of the literature but the presentations selected are important ones briefly reviewed as he considers the engineering and biophysical applications to understanding the behavior of the circulation Even though this book is not written for practicing cardiologists those in training in cardiology should know these selected principles of hydrodynamics and hemodynamics This is a good small book (first volume on biophysics and bioengineering) by Noordegraaf who has devoted much time to bioengineering

Critical Cardiac Care Volume V Edited by Ephriam Donoso M D and Stafford I Cohen M D New York 1979 Stratton Intercontinental Medical Book Corporation 248 pages Price $?8 50

The volume of *Current Cardiovascular Topics on Critical Cardiac Care* contains 13 chapters on important acute problems in cardiology Among the subjects discussed are acute myocardial infarction arrhythmias cardiogenic shock acute left ventricular congestive heart failure hypertensive crises surgical emergencies and nursing care This is a practical clinical publication which presents the current concepts and practices in diagnosis and management Readers will find this book to really consist of a series of 13 separate papers each reflecting the contributors points of view Students, interns residents and fellows in medicine and cardiology as well as general practitioners and internists would find the volume to be helpful Surely differences of opinion will become evident as each paper is studied This is a good clinical book for the practicing doctor The reader should realize that the views expressed in this publication reflect to a great extent mainly those of the authors

Cardiology Update Reviews for Physicians By Elliot Rapaport Editor in Chief New York 1979 Elsevier Publishing Company 364 pages Price $?4.95

Cardiology Update is another annual review of cardiology This volume is well written and authentic Some of the subjects included are echocardiography cardiac blood pool imaging and myocardial imaging pulmonary nuclear scanning hemodynamic studies cardiac pacing role of coronary bypass surgery aortic counterpulsation and management of hypertension The many discussions are clearly presented There is no doubt that it is much more effective to study the original publications. However this book is a concise source of discussions of important aspects of cardiology This is a good book for the busy physician

now commercially available) so as to produce two rates of infusion a basal rate of 50 μL/hr and an eightfold higher rate for mealtimes The high rate is activated by the patient pressing a guarded button on the side of the pump the rate automatically returning to the basal after a pre set period currently 17 minutes The pump receives 2 or 3 ml disposable plastic syringes filled with highly purified porcine insulin (Actrapid Novo Industri Copenhagen) diluted as necessary for each patient with 0 154 mol /L saline according to insulin requirements (see below)

The pump weighs about 300 g measures about 7 by 14 by 2 cm and is worn by the patient on a belt around the waist or in a special shoulder harness

Insulin is delivered from the infuser via a fine nylon cannula (Portex Ltd) which is implanted in the subcutaneous tissue of the anterior abdominal wall [1] This area was chosen to minimize the effects on insulin absorption known to occur when insulin is injected subcutaneously into exercising limbs Extra fine cannulae were used to avoid discharge of insulin from the tip due to random flexing and in the hope of these cannulae being more biocompatible

A single cannula has been used at the same site for 2 months without problems normally they are changed every 2 to 3 weeks Infection has not been observed at the implantation site and no tissue reaction has been felt or observed Other workers have employed a fine metal needle attached to connecting tubing for administration and this needle is changed daily by the patient

Infusion strategy

Control on the patient s conventional regime is used as the basis for setting the initial insulin infusion rate The same total daily dose is generally infused on day 1 (including mealtime step ups) and subsequently the dose is increased or decreased in approximately 20% steps according to the blood glucose levels achieved The basal infusion rate was about 1 3 to 1 8 U /hr in most of our patients other workers have quoted 12 5 to 15 mU /kg /hr the mealtime increase is activated 30 minutes before breakfast lunch and the evening meal

In a study of six patients undergoing CSII at home for prolonged periods (2 to 4 months) subjects were taught to monitor their own blood glucose with glucose oxidase reagent strips (Dextrostix) either estimating the value from the color chart provided or reading the value in a reflectance meter [11] When blood glucose readings exceeded 10 mmol /L they were instructed to initiate an extra high rate infusion When values exceeded 15 mmol /L they injected soluble insulin (Actrapid) by conventional means at a separate subcutaneous site and telephoned for advice—in case there was system malfunction or intercurrent infection for example Syringes were replaced by the patient daily

Blood glucose control

We have considered that the aim of this technique is to keep blood glucose concentrations below about 10 to 11 mmol /L (180 to 200 mg /100 ml) since there is epidemiological evidence from the Bedford and Whitehall population surveys in England[1] and from studies in the Pima Indians of Arizona[11] that significant microvascular complications do not develop in patients with post load blood glucose values below this level [1]

In (fully ambulant) diabetic subjects treated by CSII on a metabolic ward for up to 4 days mean daily blood glucose levels ranged from 5 5 to 8 4 mmol /L After initial adjustments in dose hypoglycemia did not occur as confirmed by significant reduction in the M value (an arbitrary measure of control which increases with both hyper and hypoglycemia and has extra weighting for low values')

Patients who were treated at home for 2 to 3 months (maximum 111 days) had estimated mean ± S D blood glucose levels over the entire period of between 4 8 ± 1 6 and 7 5 ± 1 6 mmol / L [1] Glycosylated hemoglobin assay confirmed that glycemic control was brought into the normal or borderline diabetic range

Intermediary metabolite control

We tend to think of diabetes as a condition characterized sine qua non by abnormalities of glucose metabolism Of course there are many other intermediary metabolites which are disordered in diabetes' and might equally or alone be responsible for the tissue complications By the same score hormones such as glucagon' and growth hormone are present in increased amounts or at least inappropriately high amounts for the level of glycemia The concept of control is obviously becoming much wider particularly as our understanding of the cause of diabetic microangiopathy is so deficient

A new approach to improved metabolic control in diabetics: Continuous subcutaneous insulin infusion

J. C. Pickup, M.A., B.M., B.Ch., D.Phil.
London, England

In recent years great efforts have been placed in developing new methods of improving control in insulin dependent diabetic patients. The main incentive is the increasing realization that the late tissue complications of diabetes, particularly the microangiopathies, almost certainly depend for their evolution on the duration and severity of the metabolic disorder of diabetes.[1] If these abnormalities of metabolism could be returned towards normal, it may then be possible to slow, halt, or reverse the progress of retinopathy, nephropathy, and neuropathy in diabetic subjects.

Unfortunately, this postulate of a link between control and complications is still an article of faith rather than a reality and the major stumbling block is the difficulty or (some would say) impossibility of achieving and maintaining metabolic near normality using conventional insulin injection therapy. Clearly what is required is a prospective controlled trial between patients randomly allocated their prevalent insulin therapy ("ordinary control") or a "super control" regime. It is to achieve the strict control of the latter type that various mechanical devices are currently being investigated.

At the outset we know that these devices must fulfil certain criteria. They should be free from complications at the point of insulin delivery to the body; one would expect prolonged intravenous administration to be unsuitable because of the risks of thrombosis and infection. They must not restrict the physical activity of the patient; bulky bedside apparatus like the so called artificial pancreas is thus excluded. Furthermore, such devices must be of low cost and applicable to most types of diabetic patients so as to enable random allocation to a fairly large trial group of patients.

Our approach has been continuous subcutaneous insulin infusion (CSII) using a dual rate portable syringe pump.[2] As will emerge, most or all of the above requirements are met by this system. The absence of a large subcutaneous pool of depot insulin, the rapid mobilization of the small volumes delivered, and the inherent flexibility of the apparatus in which the diabetic patient has control over the rate of insulin delivery commended it as a potential method of achieving long term strict control which was acceptable to the patient.

Technique

CSII is an "open loop" device, i.e., it does not employ continuous blood glucose sensing with feedback control on insulin delivery as does the artificial pancreas,[3] and for this reason alone it becomes smaller, less complex, more reliable, and truly portable. Our prototype delivery system was a modification of a quartz crystal controlled single rate syringe pump, the Mill Hill Infuser

From the Unit for Metabolic Medicine, Guy's Hospital Medical School, London, England.

insulin withdrawal if the delivery cannula is accidently removed from the subcutaneum or during intercurrent stress and illness blood glucose values can rise quickly and ketosis may develop Prompt corrective action in these circumstances must be taken on the basis of frequently monitored blood glucose estimations Until a reliable metabolic sensor is developed which will warn of loss of control outpatient use of open loop systems should probably remain a research procedure under the closest supervision

Trends

Further miniaturization of infusers will make them more acceptable to larger numbers of diabetic patients The sophistication of micropro cessor control may in the future add great flexibility of infusion rates and offer monitoring facilities and say audible warning of pump malfunction

The dream of an implantable insulin delivery system is still far from being realized New meth ods and routes of administration of insulin need to be evaluated CSII is but one approach Perhaps the greatest priority is for a controlled prospective and randomly assigned trial testing the effects of prevalent and super control on microangiopathy Only then will we be certain of the therapeutic intensity to be used toward achieving good control even with conventional treatments

It was encouraging that in our initial studies of patients treated by CSII for just 24 hours not only blood glucose but also blood lactate and pyruvate the ketone body 3 hydroxybutyrate and the major gluconeogenic precursor alanine were also returned towards nondiabetic concentrations[8] Tamborlane and associates[4] have found that plasma cholesterol triglyceride free fatty acids and branched chain amino acids are also restored to normal after 7 to 14 days of CSII

There is no information yet on whether glucagon growth hormone and other counter regulatory hormones are normalized during subcutaneous infusion

Insulin levels and doses

Fasting plasma free insulin concentrations during CSII are about 10 mU /L ' i e not far removed from those of the nondiabetic subjects Pharmacokinetic studies are beginning to indicate that the peak of circulating insulin following the mealtime step up is at about 75 minutes so that activating the prandial rate 30 minutes before a meal and allowing 45 minutes for peak glucose absorption should produce a best fit of insulin and nutrients '

It is interesting to note that work in animals indicates that about 50% of the insulin injected subcutaneously is destroyed (presumably digested by proteolytic enzymes) and so it never reaches the blood in biologically active form This probably also applies to humans One may speculate that the small volumes infused would suffer less enzymatic destruction and lead thereby to improved control

Control and microvascular disease the kidney

Radioimmunoassay of urinary albumin has demonstrated that elevated albumin excretion rates are present in some diabetic subjects even before the onset of clinical proteinuria—i e that detectable by reagent strips such as Albustix This microalbuminuria seems to be mainly caused by increased glomerular capillary permeability rather than by renal tubular dysfunction It is not known whether microalbuminuria progresses to clinical diabetic nephropathy but it must at least be taken as an index of small vessel abnormalities in diabetes

CSII has recently been used to establish 1 to 3 days of near normoglycemia in a group of seven insulin requiring diabetic subjects of long known duration of diabetes who were known to have increased urinary albumin excretion during conventional therapy Even over this short period of good control microalbuminuria was reduced in all patients and was normalized in three

These patients must presumably have structural changes in the glomerular capillaries—e g basement membrane thickening So fast was the change in permeability as to suggest functional rather than structural alterations during metabolic near normalization It follows that even in some long standing diabetic patients glomerular permeability can still be returned to normal and perhaps then nephropathy can be delayed More work is needed in this area

Control and microvascular disease the eyes

Two patients treated for 3 months by CSII had at the start of therapy rapidly progressing florid diabetic retinopathy Serial fluorescein angiograms were used to assess the response to near normoglycemia In one patient (mean ± S D blood glucose 5 9 ± 2 0 mmol /L) the progress of the retinopathy was halted and in the other case (mean ± S D blood glucose 6 1 ± 2 1 mmol /L) the retinopathy markedly regressed

Interpretations must of course be guarded in a condition known to suffer spontaneous variations in clinical course However there seems good reason to believe that even severe retinal microangiopathy may respond to super control

Cautions

One type of diabetic subject who may be unsuitable for CSII is the truly brittle patient We should be careful to define this condition as a rare syndrome of wide fast and unpredictable swings in blood glucose seemingly unrelated to food exercise or insulin administration Control does not seem to be much improved in the few brittle patients we have studied Perhaps mechanisms such as variations in subcutaneous absorption and endogenous insulin production are unchanged by this approach at least when using the present simple infusion strategy

As in all open loop systems patients treated by CSII have little or no insulin reserve The subcutaneous pool during infusion is small one factor which may explain why hypoglycemia is not a big problem compared with intensified efforts at good control using conventional depot therapy However it does mean that during absolute or relative

many significant differences from voluntary continuing smokers This investigation established empirically that a voluntary ex smoker is on the average a different kind of person from the persistent smoker and has a lower risk of CHD regardless of smoking[6] Even if no such difference had been demonstrated the drawing of conclusions about causality from comparisons between voluntary ex smokers and voluntary continuing smokers would remain illegitimate An epidemiology that sanctioned such conclusions would have no claim to be scientific

How then can we establish cause? Several attempts have been made to circumvent the difficulties that arise from the heterogeneity within human populations and the phenomenon of self selection The rigorously controlled intervention study referred to above has been approached by Rose and Hamilton Male smokers were allocated randomly (a) to the intervention group which was subjected to intensive advice to give up smoking or (b) to the normal care group which received no special advice over and above that encountered in ordinary life The "intensive advice was successful in reducing average levels of smoking in the intervention group much more than those in the normal care group However up to 1978 the death rate in the intervention group was 1 74 per 100 man years (based on 98 deaths) the rate in the normal care group was slightly but not significantly lower at 1 63 per 100 man years based on 94 deaths Findings for specific causes of death were not reported but because in the general male population of comparable age deaths from diseases of the circulatory system constitute nearly 50% of the total it seems unlikely that mortality from this cause was reduced appreciably in the intervention group These data therefore do not bolster the causal hypothesis

Twin pairs discordant for smoking habits have great research potentiality but as the Surgeon General notes 'The result has been inconclusive The main practical difficulty for this kind of investigation is of course the limitation imposed by small numbers particularly of monozygotic (MZ) twins who tend to be highly concordant for smoking habits In the largest survey published so far Cederlof and associates recorded only seven deaths from CHD in the pooled low group of smoking discordant MZ twins and nine in the pooled high group of present smoker co twins The corresponding findings fo[r] smoking discordant pairs of dizygotic (DZ) tw[in] pairs were 12 deaths (pooled low") and 26 death[s] (pooled high) This latter ratio is in line wi[th] the value expected on both causal and constitu[tional] tional views Among smoking discordant MZ tw[in] pairs the simplest constitutional hypothe[sis] would predict equal numbers of deaths in th[e] low and high smoking groups whereas pure causal theory would predict equality [of] ratios in series of similarly discordant MZ and D[Z] pairs Neither the causal nor the constitutiona[l] theory is excluded by these small numbers Th[e] trend favors constitutional and combined (caus[al] plus constitutional) interpretations

Unfortunately studies of twins remain subje[ct] to certain ambiguities even when numbers a[re] large[9] If for example deaths in smoking M[Z] twins were found to exceed those in their no[n] smoking co twins we would be unable to disti[n]guish between the *causal* hypothesis "smoki[ng] causes CHD and the *converse causal* hypothe[sis] CHD or an associated condition causes t[he] habit of smoking Equal numbers of deaths [in] the two groups would favor neither of these h[y]potheses and would point to a constitution[al] interpretation

One type of evidence that *in principle* cou[ld] distinguish between causal and converse caus[al] hypotheses on the one hand and constitution[al] hypotheses on the other is that which relates [to] secular (temporal) change On a causal hypoth[e]sis a change in cigarette consumption should [be] followed by a change in mortality rate the ma[g]nitude and sign of which should be consiste[nt] with the strength of the causal connectio[n] According to the converse causal hypothes[is] changes in CHD or an associated condition cau[se] the changes in smoking If that hypothesis hold[s] then changes in CHD mortality rate might eith[er] precede or follow corresponding changes in smo[k]ing If neither the causal nor the converse caus[al] hypothesis is valid then no systematic correl[a]tion between the trends in cigarette consumptio[n] and CHD mortality rate should be observed.

In practice secular trends abound in complic[a]tions not the least of which is the inaccuracy [of] death certification coupled with changes in th[e] International Classification of Diseases secul[ar] changes in other causal factors have also to b[e] considered By good fortune neither complicatio[n] appears to be as serious in connection with CH[D]

Smoking and coronary disease

P R J Burch PhD
Leeds England

According to Feinstein[1] a "licensed epidemiologist" can obtain and manipulate the data in diverse ways that are sanctioned not by the delineated standards of science but by the traditional practice of epidemiologists. In this absence of delineated standards it is scarcely surprising that different investigators draw diametrically opposed conclusions. Thus we find on the one hand Shimkin proclaiming "If there is any summit of achievement in cancer research during the past several decades it must be the discovery, irrefutable proof and obvious importance of the fact that tobacco smoking causes lung cancer in man and is associated with other severe hazards to health." By contrast Oldham concludes "we still do not know how cigarettes cause lung cancer nor even if we are particularly rigorous in our use of scientific logic whether they do."

A similar confusion prevails in connection with ischemic heart disease. Perhaps the most detailed exposition of the thesis "cigarette smoking is a cause of coronary heart disease" is given in the recent report by the Surgeon General. Remarkably, the thesis rests on only two types of epidemiological evidence neither of which nor both jointly are adequate to establish cause.

Inevitably the first type of evidence concerns the positive graded association that has generally but not invariably been observed between smoking and the risk of death from ischemic heart disease. Needless to say the Surgeon General is well aware that association does not necessarily imply causation: the link could be explained if people who were constitutionally liable to heart attacks were also constitutionally liable to smoke. (I should add that a positive association is neither a sufficient nor even a *necessary* condition for causation. As pointed out previously in this JOURNAL, a negative genetic association between the predisposition to smoke and the predisposition to a disease could mask a weaker causal connection.)

The Surgeon General dismisses the constitutional alternative by invoking the second type of epidemiological evidence. It should be noted however that the fact that risk in smokers reverts to normal or nonsmokers' levels after they cease to smoke is contrary to the constitutional concept. Curiously, the fact itself is denied by the entries in the Surgeon General's own Table 5—the risk of death from coronary heart disease (CHD) in each of the eight categories of persons who had discontinued smoking for five or more years lies between the levels in comparable "current smokers" and "never smokers."

However, the claim that this evidence is contrary to the constitutional concept is fallacious. If from a population of smokers certain individuals were selected *randomly* by the investigator and were successfully persuaded to give up smoking and if in all other pertinent respects they did not differ on the average from those randomly selected smokers not subjected to such persuasion and who continued to smoke then a significant reduction of mortality in the ex smoker group relative to that in controls would render the constitutional hypothesis improbable to an extent determined by the level of statistical significance. But a comparison of mortality rates in voluntary *self selected* ex smokers with that in voluntary self selected continuing smokers cannot discriminate between causal and constitutional hypotheses. A recent study of voluntary ex smokers *before* they stopped smoking showed

Myocardial infarctions unrecognized during life were frequently found at autopsy In the epidemiological study of coronary heart disease the scalar electrocardiogram is employed as one of the most useful tools in the diagnosis of this disease and frequently offers unequivocal objective evidence of its presence However it is well known that abnormal Q and QS waves in the precordial leads are seen also in persons without myocardial infarction Some of these waves are transient

Surawicz and colleagues[1] suspected that 0 5% of the electrocardiograms examined had an absent R wave in Lead V_3 Jedlicka reported that QS and QR forms were observed in Lead V_1 in 2 or 3% However the frequency of QS waves in the precordial leads without infarction is not known in the general population

This report concerns QS waves in the precordial leads found in persons of an autopsy series from a Japanese community Hisayama town during a ten year period and further shows the limitations of the scalar electrocardiogram in the diagnosis of myocardial infarction especially a old one

Materials and methods

Hisayama town is a farming community adjoining Fukuoka City on Kyushu island Japan[3] The population in this community was 6 521 in 1960 7 140 in 1965 and 7 154 in 1970 by national census Population distribution by a e and sex was not substantially different from the rest of Japan[3] The residents aged 40 years or over have participated in periodic medical examinations offered by us since the year 1961[4] Participation rates of the residents in the biennial examinations were approximately 90% except for one

as might be expected[6] Analysis implies that the rate of smoking associates inversely with the duration of the average *latent period* between the initiation of the disease process and death from CHD[5] High levels of smoking associate with a short latent period and relatively early death while nonsmokers enjoy a long latent period and a relatively long life If smoking *causes* CHD by (plausibly) shortening the latent period then because the average daily rate of smoking is much higher in young and midde aged men and women than in old persons then the latent period normally constant with age in other diseases should increase with rising age where CHD is concerned Furthermore over the period 1921 to around 1962 7 when cigarette consumption in both sexes in England and Wales was rising the latent period should have shortened the reduction should have occurred earlier in men than in women

None of these expectations of the causal theory is borne out by the mortality statistics[5] The average latent period appears to be almost constant throughout the adult range it was also nearly constant (tending to increase if anything in middle aged women) from 1921 to 1973 Nevertheless large increases in the levels of fatal CHD were recorded but these were unaccompanied by a systematic shortening of the latent period The simplest interpretation of the increases is that they were the consequence at least in part of earlier under recognition of the disease the extent of under diagnosis appears to have been fairly uniform in both sexes up to about the age of 75 A constant factor of under diagnosis would not distort estimates of the duration of the latent period

We have to consider the possibility that changes in other risk factors might have occurred so as to oppose and cancel those caused by the changes in smoking habits This is not impossible although bearing in mind the large differences in the secular changes of smoking by the two sexes and their marked age dependence the demands made of the hypothetical counter acting factors are formidable Changes in diet especially the consumption of animal fats and cholesterol cannot be invoked because on a causal hypothesis they would have exacerbated the effects of smoking over a substantial part of the period 1921 to 1973[10]

To the best of my knowledge the three kinds of investigation discussed here—random intervention trials studies of smoking discordant twins and secular trends—provide the only epidemiologically based evidence that bears critically on the causal versus the constitutional alternative The evidence available so far does not allow us to conclude that smoking causes ischemic heart disease

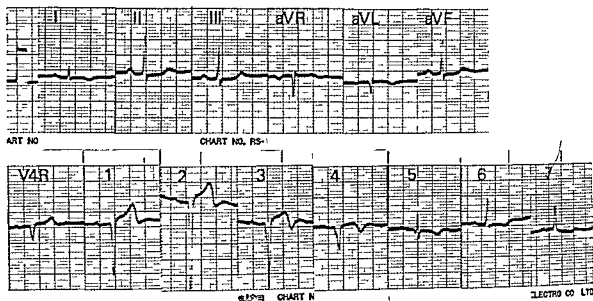

Fig 1 S A 58-year old male tracing made May 30 1963 The patient had a typical cardiac pain in October 1959 and was treated under the diagnosis of myocardial infarction This tracing shows an abnormal Q wave in Lead aV_L and QS waves in Leads V_R through V The T wave was inverted in Leads I aV_L and V and was terminally inverted in Leads V through V Postmortem examination revealed a healed myocardial infarction involving the anteroseptal and lateral walls of the left ventricle

in origin Five of these subjects showed left ventricular hypertrophy pattern by voltage criteria (RV_5 or $RV_6 + SV_1 > 35$) as well Leads in which QS waves were present are summarized in Table III Four persons showed QS waves in Leads V_{4R} and V_1 and one individual exhibited these waves in Leads V_{4R} through V_2 The other eight subjects showed an initial R wave in the leads to the right of those with QS waves A normal initial R wave in the leads farther to the right did not imply that the QS wave was pathognomonic of myocardial infarction Fig 2 reproduces the tracing of one of these individuals

Electrocardiograms of seven subjects showed QS waves in the precordial leads and a left ventricular hypertrophy pattern QS waves were present in Leads V_R and V_1 or in V_{4R} through V_2 in all of these tracings In all of them QS waves were deep and the elevated ST segment showed upward concavity T waves in the right precordial leads were upright in six individuals In the other subject QS waves in the right precordial leads were accompanied by an upright T wave in one year and by an inverted T wave in another year One subject showed clockwise rotation as well

Two individuals showed complete left bundle branch block in other years Therefore QS waves in these persons may be due to incomplete left bundle branch block One of these individuals showed left ventricular hypertrophy pattern The tracings of one case are reproduced in Fig 3

In two subjects dilatation of the right atrium was considered to be responsible for QS waves in the right precordial leads A shallow QS wave with an isoelectric ST segment was present in Lead V_1 in both of these individuals In one of them, P waves in Leads II and III were upright and sharp and a slurred r wave was present in Leads aV_R and V_{4R} Dilatation of the right atrium was recognized at autopsy (Fig 4) In the other subject P waves in Leads II and III were not large but dilatation of the right atrium and ventricle was found at autopsy

Electrocardiograms with precordial QS waves and clockwise rotation were recognized in five subjects QS waves were present in Lead V_R and V_1 in three of them QS waves were found in Leads V_{4R} through V in one year and in Leads V_R through V_3 in another year in one subject In the other individual QS waves were localized in Leads V_{4R} through V_3 in one year and in Leads V_{4R} through V_2 in three other years (Fig 5) QS waves were not deep in four of the five individuals The ST segment was elevated in four of the five subjects T waves were upright in two individuals and were inverted in the other two subjects The other subject showed ST segment elevation with an inverted T wave in one year and an

year At every periodic examination a resting electrocardiogram was taken from each participant with flat hot stylus type machines using the standard 12 leads plus Leads V_{3R} and V_7 The recording speed was 25 mm per second All of the electrocardiograms were read by Dr Hirota at each examination For this study the electrocardiograms of the autopsied persons were reexamined by Drs Hirota and Hiyoshi.

All efforts were made to obtain an autopsy on all of the deceased persons in this community[2] The number of autopsied persons aged 40 years or over at the time of death was 339 (181 men and 158 women) during the first ten year period from Nov 1 1961 to Oct 31 1971 Distribution of these by age and sex is presented in Table I The mean *autopsy rate was approximately 84%*

Heart and coronary arteries were examined after fixation in 10% formalin The subepicardial coronary arteries were cut transversely at 2 to 3 mm intervals and both of the ventricles were also cut transversely at 1 cm intervals from the apex to the base Histological examination was made on one of the transverse sections containing both papillary muscles and also on the section containing suspected lesions A zone of necrosis or scarring of 1 cm or more in the maximal dimension was called myocardial infarction Lesions of histological age of 5 weeks or more using the criteria described by Mallory and colleagues were considered old

Results

Electrocardiograms had been taken from 308 (161 men and 147 women) of the 339 autopsied persons at least once during the periodic examinations QS waves in the precordial leads were recognized in 46 persons (21 men and 25 women) Excluding WPW syndrome and complete bundle branch block none of the features of the electrocardiogram other than QS and abnormal Q waves was considered in the selection of cases Distribution of individuals by the number of tracings displaying precordial QS waves is presented in Table II

There were nine individuals exhibiting old myocardial infarction (anteroseptal six anteroseptal lateral one circumferential two) QS waves were limited to the Lead V_{3R} through V_2 in two V_{4R} through V_3 in four and V_{3R} through V in three In all of them QS waves were accompanied by ST segment elevation excluding Lead V_{3R} QS waves were deep in all subjects Abnormal Q wave in the lead farther to the left was found in only one of these nine individuals In all but this one subject the q wave was not recognized in the left precordial leads In eight subjects the elevated ST segment showed upward concavity In the other one the ST segment showed upward convexity but review of the history revealed no evidence suggestive of acute myocardial infarction at the time of this examination The T wave was upright or terminally inverted in the leads with a QS wave in eight individuals In the other subject the T wave was upright or terminally inverted in Leads V_{3R} through V_2 and was inverted or terminally inverted in Lead V_3 showing the QS wave In four patients precordial QS waves were recorded at the examination in 1961 In two individuals they appeared at the third examination following symptoms suggestive of myocardial infarction In the other three subjects they appeared in the later tracings but symptoms suggestive of myocardial infarction were not revealed by a review of the history Fig 1 is a reproduction of the tracing of one of the infarction cases

In 13 persons without myocardial infarction q waves in Leads V_5 V_6 or V_7 suggested that QS waves in the right precordial leads were positional

Table I Age and sex distribution of autopsied persons by 10 year age groups

Sex	Age groups (years) 40-49	50-59	60-69	70-79	80-89	90-99	Total

cardial infarction case can be normal in some years[1 1]

The most important criterion of the scalar electrocardiogram for the diagnosis of old infarction is the presence of QS and/or abnormal Q waves However cases of QS waves in the precordial leads especially in the right precordial leads without myocardial infarction were frequently reported An abnormal Q or QS wave in the right precordial leads was reported to be recognized in the cases of septal infarction,[16] left ventricular hypertrophy,[1 17 19] right ventricular hypertrophy and dilatation [19 2] right atrial dilatation[19] primary myocardial disease amyloidosis[1 r n] acute ischemia of the myocardium[2 7] left bundle branch block left anterior hemiblock[8] septal focal block clockwise rotation pulmonary emphysema[18 30 31] deformity of the thorax[19] allergic shock[3] acute adrenal failure[18] acute pancreatitis[33] cerebrovascular diseases[31 3 35] elec

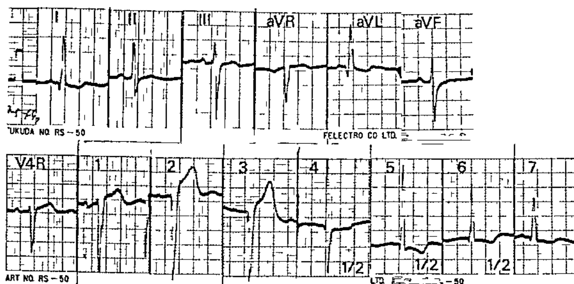

Fig 2 U K 70 year old male tracing made May 14 1962 This tracing shows a left ventricular hypertrophy pattern Lead V shows a QS wave with embryonal r wave Leads V through V show a q wave Postmortem examination revealed left ventricular hypertrophy (heart weight 510 gm)

isoelectric ST segment with an upright T wave in another year

Electrocardiograms of eight individuals showed QS waves in the right precordial leads but they were otherwise within normal limits Localization of precordial QS waves is summarized in Table IV In all of these subjects initial r waves appeared in Lead V or V_3 and increased in amplitude to an R wave in leads farther to the left QS waves of six subjects were small Autopsy revealed slight to severe pulmonary emphysema in five individuals subdural hematoma in one liver cirrhosis in one and acute intoxication with insecticide in one subject In one individual having pulmonary emphysema left ventricular hypertrophy (heart weight 335 gm) was recognized at autopsy

Electrocardiograms with precordial QS waves were tabulated by the localization of a QS wave and the presence or absence of myocardial infarction (Table V) The categories for the localization are not mutually exclusive This table indicates that QS waves localized to only one Lead—V V or V_3—were frequently not due to myocardial infarction All of the electrocardiograms with a QS wave in one Lead (V_2 *or* V_3) or in leads V *and* V_3 had a q wave in the left venticular leads Therefore these QS waves were considered to be positional Even if an initial r wave was present in leads farther to the right these electrocardiograms should not always be interpreted as being due to myocardial infarction solely on the basis of QS waves Electrocardiograms with QS waves in Leads V and V_2 should also be carefully interpreted

QS waves with an embryonal r wave were found in six subjects All of them had an embryonal r wave on the descending limb of the QS wave In two of them myocardial infarction was recognized at autopsy All of the subjects with myocardial infarction had deep QS waves but persons without infarction also frequently showed deep QS waves Development of the precordial QS waves in the second third or later tracing was found in both groups with and without myocardial infarction

Discussion

Electrocardiogram shows age trends [6] sex differences [8] and racial differences Constitutional differences also induce electrocardiographic differences The electrocardiogram is not sensitive to coronary atherosclerosis [6 10 1] Myocardial infarction develops in only a small number of the cases of coronary atherosclerosis

The clinical diagnosis of myocardial infarction without electrocardiographic evidence has been shown to be inaccurate However it is well known that there are difficulties in the diagnosis of myocardial infarction by scalar electrocardiogram Rigid criteria will improve specificity but will reduce sensitivity The tracings of the myo

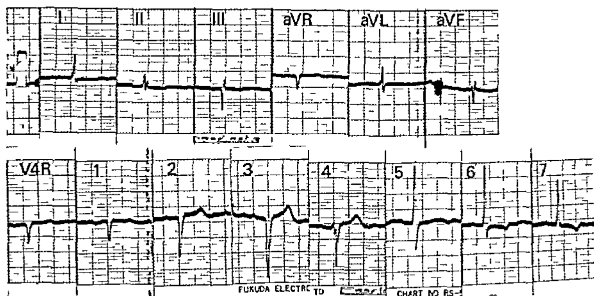

Fig 5 F T 83 year old female tracing made May 21 1962 This tracing shows QS waves in Leads V through V and clockwise rotation The subject died of hemorrhagic brain infarction in December 1962. Heart weight was 280 gm

trophy In clockwise rotation the interventricular septum rotates and the right septal surface faces anteriorly or even slightly toward the left and therefore the septal vector seems to be directed toward the left Myers and co workers[16] maintained that in left ventricular hypertrophy cardiac rotation brought the right atrium beneath the sternum and tilted the mitral orifice to the right and foward and that in such a position left ventricular cavity potential could be recorded in Leads V_1 and V Surawicz and associates[1] were of the opinion that in left ventricular hypertrophy the initial vector forces were directed downward which caused the initial negative deflection of the QRS complex in Leads V_3 andV_4 and that the tracings recorded from the position below the standard level of V_3 and V_4 showed an initial R wave

Epstein and Wasserburger [8] reported a case of pulmonary emphysema where QS waves in Leads V_1 through V_6 were attributed to the low level of

*The categories for the localization are not mutually exclusive.

the diaphragm In this case tracings taken from the position two intercostal space below the standard level were normal Some of our cases suggested that absence of the initial R wave in the precordial leads resulted from a transitional zone effect Absence of the initial R wave in the right precordial leads can theoretically occur either because of a change of heart position with relation to the electrode or because of a change of the electrode position with relation to the heart[1]

From the foregoing it would appear that the diagnosis of myocardial infarction must never rest solely upon a single tracing The electrocardiographic findings should be evaluated in the light of the clinical findings and the history The

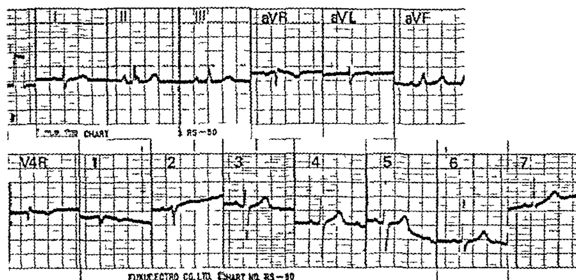

Fig 4 K M 80-year old male tracing made May 28 1963 P waves in Leads II and III were upright and sharp R waves in Leads aV_R and V were small but slurred A QS wave was present in Lead V Autopsy revealed a patent foramen ovale accompanied by dilatation of the right atrium and a dilated and thickened pulmonary artery

trolyte imbalance [1, 6, 36] normal heart WPW syndrome [35] etc

Our cases did not suffer from acute adrenal failure acute pancreatitis acute cerebrovascular diseases asthmatic attack or angina pectoris at the time of examination

Infarction in the left half of the interventricular septum can produce a QS wave in the right precordial leads and disappearance of a q wave in the left ventricular leads These changes are attributed to disappearance of the left to right septal vector The presence of a normal initial r wave in Lead V_{3R} indicates that a QS pattern in Leads V_1 and V is the result of infarction and not a normal variant and the abnormal Q waves demonstrated in leads farther to the left constitute indirect evidence that the QS complexes in Leads V_1 and V are also the results of infarction [16] Myers and associates reported that a smooth QS wave in Leads V and V might occur as a normal variant but that a Q wave followed by a small R wave or R wave equivalent and then by a deep S wave was representative of septal infarction Our cases however suggest that the notched QS wave in the right precordial leads are not pathognomonic of septal infarction The ST segment and T wave are also changed in the acute stage of infarction The level of the S T junction and the contour of the ST segment is of little or no aid after healing [1]

electrocardiogram may also be better interpreted on the basis of pattern reading in the mass population survey for coronary heart disease Persons displaying precordial QS and abnormal Q waves in the standard electrocardiogram should be evaluated by further examination including tracings taken from the lower levels Minnesota Code 1 1 [1] seems to have some difficulties in the diagnosis of myocardial infarction Blackburn and colleagues[6] stated that false positive labels of infarction on the basis of Q and QS criteria would be reduced in the final tabulation by excluding subjects with chronic pulmonary disease The false positive diagnosis of myocardial infarction by QS waves in the right precordial leads would be further reduced by excluding persons with q waves in the left precordial leads

As the accuracy of a diagnostic test is influenced by the prevalence of the disease of interest in the population studied [13] the precordial QS waves may have a higher diagnostic value in the population with higher prevalence of coronary heart disease

Summary

During a ten year period from November 1 1961 to October 31 1971 339 residents aged 40 years or over at death were nonselectively autopsied in a Japanese community Hisayama town (mean autopsy rate 84%) One or more standard 12 lead ECGs plus V_R and V electrocardiograms taken at periodic medical examinations were available for 308 of them In 46 persons QS waves were localized in one or more leads from V to V By transverse sectioning of the hearts old myocardial infarction extending into the interventricular septum was found in nine of these 46 persons Frequency of myocardial infarction cases in each category for QS localization was as follows Lead V_1 to V_4 three of three Leads V to V six of nine Leads V and V_2 three of 15 Leads V and V_3 none of two Lead V none of one Lead V_2 one of eight and Lead V one of 25

Aortic root motion on m mode echocardiography is influenced by left atrial volume change. Analysis of this motion reveals that in diastole there is both an early and late diastolic posterior motion separated at slow heart rates by a period of little motion in mid diastole. This early diastolic motion has been quantified by an atrial emptying index which is the fractional change in diastolic motion of the posterior aortic root in the first one third of diastole.[2] This index is abnormal in mitral stenosis and inversely correlated to the degree of stenosis. However, in addition to left atrial emptying across the open mitral valve, atrial volume change during this period should reflect left atrial filling from pulmonary venous flow.[3] Late diastolic posterior motion of the aortic root occurs as a consequence of left atrial contraction. During atrial systole, however, little or no left atrial filling occurs and, ignoring the possibility of pulmonary venous reflux, left atrial volume change should reflect late diastolic events in the left ventricle. In this paper we have examined the hemodynamic determinants of late diastolic posterior motion of the aortic root following the P wave of the ECG in normal individuals and patients with left ventricular hypertrophy in whom altered patterns of left ventricular filling commonly occur.

Materials and methods

Standard m mode echocardiography was performed on 25 individuals (Group 1) including 21 consecutive normal volunteers and four patients with atypical chest pain with normal coronary arteries and left ventricular function, and on 15 patients (Group 2) with left ventricular hypertrophy (IVS or PW > 11 mm.) secondary to aortic stenosis, hypertension, or idiopathic hypertrophic subaortic stenosis. In addition, the echocardiograms of 10 patients (Group 3) with a clinical diagnosis of mitral stenosis who were in normal sinus rhythm were reviewed. Patients were included only if high quality echocardiograms of the aortic root and left ventricle could be obtained. Patients with left ventricular asynergy, significant coronary artery disease, or more than mild aortic or mitral regurgitation were excluded. The aortic root was recorded at 50 mm./sec. in a sweep from the anterior mitral valve leaflet at the level of the aortic valve. The gain was diminished until a single strong echo could be reflected from each side of the aortic root. Echocardiograms of the aortic root were rejected when several echoes were reflected from both sides of the aortic root or if the anterior and posterior aortic roots were not moving parallel in late diastole. The slope and excursion of the late diastolic posterior motion of the posterior aortic root following the P wave on

Fig 3 Representative echocardiogram of the aortic root in a patient from Group 2 *The arrow is pointing to the LV pressure trace* *ECG* = electrocardiogram *AR* = aortic root *LA* = left atrium

ic and hemodynamic data were available the aortic root slope was correlated with various left atrial and left ventricular parameters Echocardiographic and hemodynamic data from the 16 patients studied at the time of catheterization are given in Table II A significant inverse linear correlation was found between the aortic slope and EDCS ($r = -0.74$ $P < 0.01$) as seen in Fig 5 Because of scatter in the data we did not attempt in the individual patient to predict chamber stiffness from the value of the aortic root slope There was no relationship between aortic slope and either left atrial size total aortic excursion pre A wave pressure A wave height the atrial contribution to LV filling (ΔD) end diastolic dimension of the left ventricle LV wall thickness or left ventricular end diastolic pressure

Discussion

The aortic root and left atrium are easily visualized with m mode echocardiography Although excursion of the aortic root has been related to stroke volume Strunk and co workers were the first to demonstrate that movement of the posterior aortic root during early diastole reflects left atrial volume change Presumably this is related to the relative immobility of the left atrial wall except anteriorly where it comes into contact with the ascending aorta Furthermore Strunk and associates devised an atrial emptying index which measured the rate of emptying of the left atrium in early diastole This index is decreased in the presence of mitral stenosis and also in patients with increased pulmonary capillary wedge pressures and no mitral stenosis' The determinants of late diastolic motion of the aortic root have not been previously characterized In sinus rhythm late diastolic posterior motion of the aortic root is directly related to left atrial contraction and in patients with complete heart block it can be shown to follow the P wave of the electrocardiogram occurring anywhere in ventricular diastole ' It also disappears in the presence of atrial fibrillation We found the slope of late diastolic posterior motion correlated best with a modulus of late diastolic chamber stiffness of the left ventricle but not with the atrial contribution to left ventricular filling or the change in left ventricular pressure following atrial contraction A possible explanation for this association is contained in the appendix

During atrial systole the rate of left atrial volume change (ignoring pulmonary venous reflux) equals the rate of left ventricular volume change as there is no left atrial filling during th period Although the aortic root slope represents

Sixteen patients the four with atypical chest pain in Group 1 and 12 patients in Group 2 in whom high quality echocardiograms of the aortic root and left ventricle could be obtained during diagnostic catheterization were further evaluated with invasive studies Informed consent was obtained in each patient prior to study Either before injection of any contrast agent or at least 20 minutes following completion of catheterization when heart rate and left ventricular end diastolic pressure had returned to baseline a No 8 Millar catheter was externally calibrated and inserted via the brachial artery into the left ventricle As the aortic root slope represents a late diastolic event it was compared with pressure and dimension measurements of the left ventricle in late diastole only Simultaneous pressure and echo dimensions of the left ventricle were obtained before the A wave of the left ventricular pressure trace and at the A wave peak if present (12 patients) or at end diastole (four patients) at a paper speed of 100 mm /second Chamber stiffness in late diastole (EDCS) was determined as $\Delta P/\Delta D$ and divided by the average pressure ($\bar{P}$) This assumes an exponential pressure dimension relationship in late diastole ($\Delta P/\Delta D = K\bar{P}$) even though this curve may be slightly altered by viscous forces occurring at the time of atrial systole[5] McLaurin and colleagues and recently our laboratory have validated the use of dimension in place of volume in determining EDCS At least three consecutive beats were averaged and analyzed with the aid of a Graf pen sonic digitizer and PDP 11/70 computer The calculation of stiffness using this methodology has been previously described All aortic root slopes were calculated at the same heart rate and left ventricular pressure as the other echocardiographic and hemodynamic parameters and were analyzed independently of the hemodynamic data

Statistical analyses were performed using the two tailed t test for difference in means Least squares linear regression analyses was performed and r values were calculated All results are expressed as the mean ± standard error of the mean

Results

Basic echocardiographic data from Groups 1 and 2 are contained in Table I Patients in Group 2 were significantly older had larger left atrial sizes faster heart rates thicker interventricular septums and posterior walls and slower E to F slopes of the mitral valve than in Group 1 patients (all with $P < 0.05$) The total aortic root excursion was significantly greater in Group 1 PR intervals were similar between the two groups The individual aortic root slopes for Groups 1 and 2 are seen in Fig 2 The mean slope of Group 1 was slightly greater than Group 2 although this was not statistically significant A representative aortic root echocardiogram from a patient in Group 2 with a slow aortic root slope is shown in Fig 3 In both groups there was no correlation between either age or heart rate and aortic root slope Patients with mitral stenosis (Group 3) had significantly slower aortic root slopes (28 8 ± 4 5 mm /sec) than in Group 1 or Group 2 ($P < 0.001$) Left atrial sizes in Group 3 (29 ± 1 3 mm /M²) were significantly greater than left atrial sizes in Group 1 or Group 2 ($P < 0.01$) A representative echo of a patient with mitral stenosis is seen in Fig 4 As catheterization data were not available for most of the patients with mitral stenosis no attempt was made to correlate the aortic slope with the degree of stenosis

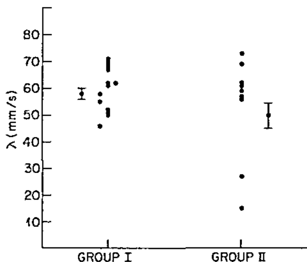

Fig 2 Illustration showing the individual aortic root slopes (λ) for all patients in Groups 1 and 2 The mean ± SEM for both groups is also shown There wa no statistically significant difference between the mean aortic root slopes in the two groups.

Although the mean slope in Groups 1 and 2 were similar a wide range of values was present in Group 2 (15 to 73 mm /sec) Therefore in the 16 patients in whom simultaneous echocardiograph

ΔP = "A" wave height in millimeters of mercury which is the numerator of th stiffness equation $\bar{P}$ = denominator of stiffness equation which is the average pressure during d terminat on of stiffness EDCS = late diastolic chamber stiffness which is equal to $\frac{\Delta p \ \Delta D}{\bar{P}}$ where ΔD is the change in the echocardiographic internal dimension.

left atrial dimensions encountered in our patients Therefore as there may be a linear relationship between atrial dimensions and left atrial angiographic volumes in the range of left atrial dimensions measured a change in dimension of the left atrium would be proportional to a change in volume The aortic root slope as a measure of left atrial volume change would then be independent of left atrial size per se and normalization for left atrial size would not be indicated

It is possible that the differences in slopes found in our patients were primarily related to differences in left atrial contractility On the other hand as we found no relationship between the aortic slope and either left atrial size the posterior aortic root excursion or A wave height differences in the force of left atrial contraction seem unlikely to explain all our findings However it is likely that in patients in Group 1 and Group 2 with similar aortic slopes the higher left ventricular pressures in Group 2 imply a more forceful left atrial contraction as a compensatory mechanism for maintaining equal rates of left atrial emptying

Although we ignored pulmonary venous reflux ultrasonic flow transducers implanted in the pulmonary veins of dogs have shown a brief retrograde pulse during left atrial contraction.[1] Utilizing Doppler techniques retrograde flow in the jugular vein has been demonstrated in patients with abnormal right ventricular compliance and large right atrial A waves[1] However even if pulmonary venous reflux is greatest in patients with large A waves in their left ventricular tracings many of these same patients have increased forward flow into the ventricle from a large atrial contribution to filling In these patients pulmonary venous reflux may be of little importance in determining the aortic root slope

In conclusion we have studied the hemodynamic correlates of late diastolic motion of the aortic root The slope of this line is decreased in mitral stenosis and in the absence of mitral stenosis may be related to diastolic properties of the left ventricle This parameter is easily determined and with future work could become a potentially useful noninvasive index of late diastolic events in the left ventricle

Summary

Motion of the posterior aortic root on echocardiography is related to left atrial volume chan e Early diastolic posterior motion of the aortic root

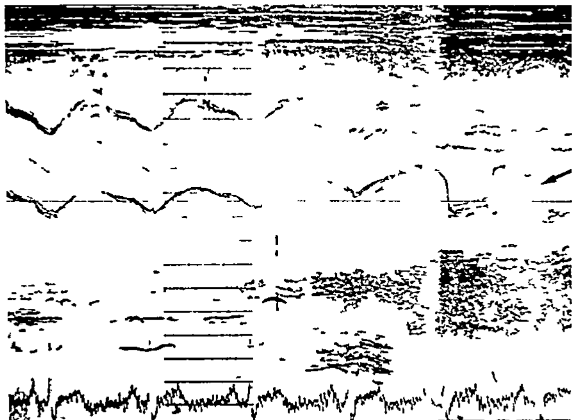

Fig 4 Representative echocardiogram of the aortic root and anterior mitral valve leaflet *(arrow)* from a patient in Group 3

a rate of left atrial dimension change (ΔD/ΔT LA) and not a volume change it seems apparent that this slope should be governed by the filling characteristics of the left ventricular chamber In turn left ventricular diastolic filling is dependent on the chamber stiffness over that portion of the pressure volume or pressure dimension curve measured It would be most informative to have varied left ventricular pressure by changing load ing conditions while measuring chamber stiffness and the aortic root slope to see if a change in slope might accurately predict a change in late diastolic chamber stiffness

There was a good relationship between stiffness and the aortic root slope in the series of patients studied However because of scatter in the data we did not attempt to predict stiffness in the individual patient This suggests that the aortic root slope might also be dependent on other variables not measured—e g left atrial size left atrial contractility and pulmonary venous reflux In this study we did not normalize the aortic root slope for left atrial size since the relationship between left atrial dimension and left atrial vol

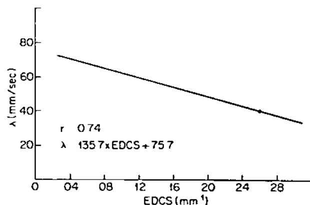

Fig 5 Graph showing the correlation between the aortic root slope (λ) from the 16 patients studied invasively versus end-diastolic chamber stiffness *(EDCS)*

ume has not been clearly defined In children Yabek and co workers [1] found that left atrial echo dimensions and left atrial volumes were related by the equation y = 8 1 x [1] Although this equation is exponential on review of their data from Table I it could also be fit by a straight line with an r value of 0 89 over the same range of

Appendix

1 During atrial systole

$$\frac{\Delta V}{\Delta T}(LA) = \frac{\Delta V}{\Delta T}(LV)$$

If there is no left atrial filling during atrial systole and ignoring pulmonary venous reflux

2 $$\frac{\Delta D}{\Delta T}(LA) \propto \frac{\Delta V}{\Delta T}(LA)$$

If there is a linear relation between atrial dimension and volume[11]

3 $$\frac{\Delta P}{\Delta V}(LV) = K\overline{P} \text{ or } \Delta V = \frac{\Delta P}{K\overline{P}}$$

If an exponential relationship exists between P and V during diastole in the left ventricle

4 Substituting for ΔV in equation 1 the expression $\frac{\Delta P,}{K\overline{P}}$

then $$\frac{\Delta D}{\Delta T}(LA) \propto \frac{\Delta V}{\Delta T}(LA) = \frac{1}{K} \times \frac{\Delta P}{\overline{P}} \times \frac{1}{\Delta T}$$

Therefore $\frac{\Delta D}{\Delta T}$ (LA), which is the aortic root slope is inversely related to

K We found no relationship between the aortic slope and either $\overline{P}$ of ΔP This is probably related to the fact that in this series of patients

$\frac{\Delta P}{\overline{P}}$ remained relatively constant with a wide range of pressure

reflects both LA emptying and filling and has been measured as the atrial emptying index To study late diastolic motion of the aortic root we measured the slope of posterior motion of the aortic root after left atrial systole (following the P wave of the ECG) in 25 subjects without heart disease (Group 1) in 15 patients with left ventricular hypertrophy due to pressure overload (Group 2) and in 10 patients (Group 3) with mitral stenosis The aortic root slope measured (mean ± SEM) 58.0 ± 1.9 mm/sec in Group 1 50.6 ± 4.5 mm/sec in Group 2 (NS vs 1) and 28.8 ± 4.5 mm/sec in Group 3 ($p < 0.01$ vs 1 or 2)

In 16 patients (four in Group 1 and 12 in Group 2) studied at catheterization an inverse correlation ($r = -0.74$ $p < 0.01$) was found between the aortic root slope (over a range of 30 to 73 mm/sec) and left ventricular late diastolic chamber stiffness measured with simultaneous left ventricular echo and high fidelity pressure recordings No correlation was found between this slope and either left atrial size total aortic root excursion left ventricular pressure pre A wave height of the A wave end diastolic pressure or the atrial contribution to left ventricular filling Therefore the aortic root slope in late diastole is decreased in mitral stenosis and in the absence of mitral stenosis it appears to be related to late diastolic properties of the left ventricle

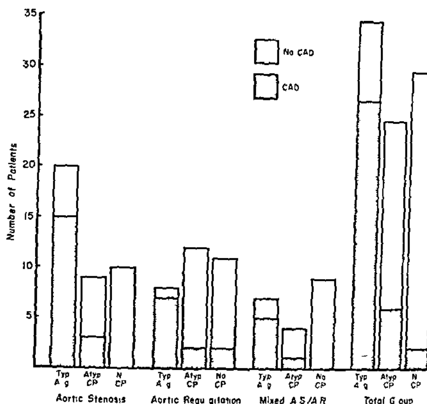

Fig 1 The correlation of angina pectoris and coronary artery disease (CAD) in patients with aortic stenosis (A S) aortic regurgitation (A R) and mixed aortic stenosis and aortic regurgitation (A S/A R) Typ Ang = typical angina pectoris Atyp CP = atypical chest pain No CP = no chest pain

The degree of aortic regurgitation was assessed by root aortography in the left anterior oblique projection[17] Aortic regurgitation was graded as trivial (1+) mild (2+) moderate (3+), and severe (4+) Trivial regurgitation was defined as a mall amount of dye entering the left ventricle during diastole and washing out during systole and severe regurgitation was assumed when good opacification of the left ventricle was seen during the first diastole with the dye remaining in the left ventricle for several beats

The pressures were recorded with a fluid filled manometric system the zero reference point being the mid chest level pressures were recorded on an Electronics for Medicine photographic recorder The aortic valve pressure gradients were measured by recording simultaneous left ventricular and aortic pressures with a double lumen catheter or with two separate catheters The left ventricle was entered retrogradely through the aortic valve or via the transseptal route

Typical angina pectoris was defined as chest discomfort lasting for 1 to 15 minutes precipitated by effort or emotion exposure to cold or at rest which was promptly relieved by rest or nitrates

Atypical chest pain was defined as prolonged chest discomfort lasting sometimes for hours and usually occurring at rest and not relieved by nitrates

The aortic valve area was calculated by means of the Gorlins formula[18]

On the basis of the predominant aortic valve lesion the patients were divided into three sub groups (1) patients with severe aortic stenosis (with a valve area equal to or less than 0 55 cm /M with mild or no associated aortic regurgitation) (2) patients with predominant aortic regurgitation (moderate to severe aortic regurgitation with no pressure gradient or with less than 20 mm Hg peak gradient across the aortic valve) and (3) patients with mixed aortic valve disease (systolic pressure gradient of equal or greater than 20 mm Hg with moderate or severe aortic regurgitation)

Statistical analysis was performed by the chi square method and by the Student s t test

Results

There was a total of 90 patients for our final analysis Sixty patients (66%) had chest pain of

Angina pectoris and coronary artery disease in patients with severe aortic valvular disease

Angina pectoris is a common symptom of both aortic valve disease and coronary artery disease.[1-4] In both conditions the angina is due to an imbalance between oxygen supply and demand. The presence of significant coronary artery disease in patients with aortic valve disease is of predictive value for the operative mortality rate during aortic valve replacement. A recent report indicated that patients with aortic valve disease associated with coronary artery disease undergoing aortic valve replacement and concomitant coronary bypass surgery had better short- and long-term prognoses than did patients who had only aortic valve replacement and no bypass for their coronary artery disease. Therefore, when we consider the possibility of aortic valve surgery it is important to know whether there is associated coronary artery disease. There is, however, a significant controversy in the reported prevalence of angina pectoris or associated coronary artery disease in patients with aortic valve disease.[5, 10-15] The purpose of this study is to review our experience as to the prevalence of angina pectoris and associated coronary artery disease in a group of 90 patients 40 years of age and older with significant aortic valve disease who were studied in our cardiac catheterization laboratory.

Materials and methods

The records of all patients with cardiac catheterization diagnoses of aortic valve disease were reviewed. Only patients over 40 years of age were included in our study. Patients who had more than trivial mitral insufficiency, mitral stenosis, or who had had previous coronary or valve surgery were excluded. Ninety consecutive patients were finally selected for the study. All patients had complete right and left heart catheterization, left ventriculography, aortography, and coronary arteriography. Left ventriculograms were performed in a 30 degree right anterior oblique projection with 45 to 50 ml of 76% meglumine diatrizoate (Renografin). Aortograms were performed in the left anterior oblique projection and coronary arteriography was performed in multiple left and right anterior oblique projections with the Sones and the Judkins technique. Coronary arteriography is routinely performed in our institution in all adult patients with aortic valvular disease.

The cine films were recorded with a 35 mm camera at 30 seconds and were reviewed by at least two angiographers. We calculated the left ventricular volumes using the right anterior oblique projection left ventriculograms.[16] Cardiac output was determined by the dye dilution technique and by the Fick method. The ejection fraction was calculated as angiographic stroke volume divided by the end-diastolic volume. The regurgitant fraction was calculated as the fraction of the total angiographic cardiac output minus the forward cardiac output divided by the total angiographic cardiac output.

2.7 ± 0.6 L/min/M² in the coronary artery disease and non coronary artery disease subgroups respectively The left ventricular ejection fraction was 52 ± 6% and 57 ± 11% for the coronary artery and non coronary artery disease subgroups respectively

Patients with mixed aortic stenosis and aortic regurgitation There were 20 patients in this group 14 men and six women There were six patients (30%) with associated coronary artery disease (mean age 67 ± 7.3 years) and 14 patients (70%) without associated coronary artery disease (mean age 57 ± 12.4 years) Of the six patients with coronary artery disease two had one vessel disease three had two vessel disease and one had three vessel disease (Table I) In the subgroup with associated coronary artery disease all patients had chest pain (five typical angina and one atypical chest pain) Five patients (83%) had one or more risk factors for coronary artery disease and four patients had dyspnea on exertion (New York Heart Association Class III or IV) None of the patients had syncope

There was electrocardiographic evidence of myocardial infarction in one patient In the subgroup without associated coronary artery disease five patients (36%) had chest pain (two typical angina and three atypical chest pain) Seven patients (50%) had one or more risk factors for coronary artery disease Six patients (43%) had dyspnea on exertion (New York Heart Association Class III or IV) three patients (21%) had syncope and none had electrocardiographic evidence of myocardial infarction

On fluoroscopic examination calcification of the aortic valve was seen in 67% and 71% in the subgroups with and without coronary artery disease respectively The hemodynamic data are shown in Table I In the subgroup with coronary artery disease the mean systolic pressure gra

these 35 had angina pectoris (39%) and 25 had atypical chest pain (Fig 1) while only 35 of the 90 patients (39%) had associated coronary artery disease Thirty three of the 35 patients (94%) with coronary artery disease had chest pain (typical angina in 27 and atypical chest pain in six) Two patients with coronary artery disease did not have chest pain One of these patients had 55 to 60% narrowing of the left anterior descending coronary artery the history of the other patient was difficult to obtain because of language difficulty and his chest discomfort could not be evaluated properly Of the remaining 55 patients without coronary artery disease 27 (49%) had chest pain (eight typical angina and 19 atypical chest pain)

The detailed clinical hemodynamic and angiographic data for all groups of patients are summarized in Table I Each of the three groups was further subdivided into two subgroups patients with coronary artery disease and those without

Patients with predominant aortic stenosis There were 39 patients in this group 26 men and 13 women Their ages ranged from 43 to 79 years (mean 65 ± 10 years) Associated significant coronary artery disease was present in 18 patients (46%) one vessel was involved in four patients two vessels were involved in eight patients three vessels were involved in three patients and the left main coronary artery was involved in three patients The remaining 21 patients had no associated coronary artery disease All the 18 patients with associated coronary artery disease had chest pain (typical angina 15 atypical chest pain three) Of the 21 patients without associated coronary artery disease 11 patients (52%) had chest pain (typical angina five atypical chest pain six)

One or more risk factors for coronary artery disease were present in 16 of the 18 patients (89%) with associated coronary artery disease and in 17 of the 21 patients (81%) without coronary artery disease The risk factors were hypertension diabetes mellitus smoking hyperlipidemia and a family history of coronary artery disease under the age of 60 Dyspnea on exertion was present in 14 patients (78%) with coronary artery disease and 14 patients (67%) without coronary artery disease Syncope was present in five (28%) and eight patients (38%) with and without coronary artery disease respectively

Electrocardiographic evidence of myocardial infarction was present in two patients in each subgroup Calcification of the aortic valve was present in 16 patients (89%) with coronary artery disease and 19 patients without The average mean aortic valve pressure gradient was 57 ± 24 mm Hg in the coronary disease subgroup and 75 ± 23 mm Hg for the subgroup without coronary artery disease The average aortic valve area was 0 35 ± 0 11 cm²/M² for the coronary artery disease and 0 28 ± 0 07 cm²/M² for the noncoronary artery disease subgroups The remainder of the hemodynamics are shown in Table I

Patients with predominant aortic regurgitation There were 31 patients in this group 23 men and eight women Eleven patients (35 5%) had associated coronary artery disease and 20 patients (64 5%) did not The ages of patients in the coronary artery disease subgroup ranged from 43 to 76 years (mean age 55 5 ± 7 4 years) and in the non coronary artery disease subgroup ages ranged from 46 to 71 years (mean age 54 5 ± 8 7 years) One vessel disease was present in four patients (36%) and two vessel disease was present in seven patients (64%) No patient had three vessel disease Chest pain was present in nine patients (typical angina seven atypical chest pain two) and in 11 patients (typical angina one and atypical chest pain 10) in the coronary artery disease and noncoronary artery disease subgroups respectively

Risk factors for coronary artery disease were present in nine patients (82%) in the coronary artery disease subgroup and in 16 patients (80%) in the non coronary artery disease subgroup

Exertional dyspnea was present in four patients (36%) with coronary artery disease and in 15 patients (75%) without Syncope did not occur in any of the patients with coronary artery disease but it did occur in six patients (30%) without coronary artery disease

Calcification of the aortic valve was present in four patients (36%) in the coronary artery disease subgroup and in five patients (25%) in the non coronary artery disease subgroup There were no significant differences in the mean pressure gradient across the aortic valve in the coronary artery and non coronary artery disease subgroups The end-diastolic pressure of the left ventricle was 27 ± 13 8 mm Hg in the coronary artery disease subgroup and 19 ± 10 mm Hg in the non coronary artery disease subgroup The cardiac index was 2.5 ± 0 4 L/min/M² and

artery disease The group with aortic regurgitation had one or two vessel disease This may explain why 83% of the patients with aortic stenosis had typical angina in contrast to 64% of patients with aortic regurgitation Although Linhart and colleagues[14] suggested that patients with *aortic regurgitation may be less prone to develop* coronary artery disease the less extensive disease in the patients with aortic regurgitation in our group may in part be explained by the fact that the patients were almost 10 years younger than patients with aortic stenosis (mean age aortic stenosis 65 ± 10 1 years vs aortic regurgitation 55 5 ± 7 4 years) It is of interest also to note that one vessel disease was present in 29% of the 35 patients with aortic valve disease in contrast to 21% with one vessel disease of all the patients with coronary artery disease referred for coronary arteriography in our laboratory

Similar findings of a low incidence of multivessel disease were reported by Graboys and Cohn [13] The prevalence of coronary artery disease in our patients with typical angina pectoris was 77% in contrast to patients with atypical chest pain with only a 25% rate of coronary artery disease ($\underline{P} = 0\,001$) These findings agree with those of Paquay and associates [26] who reported that in patients with aortic valve disease the more typical the angina the more likely these patients are to have coronary artery disease Hancock,[9] in the most recent report of his experience with a large series of patients with aortic stenosis commented on the significance of angina associated with dyspnea He reported that angina occurring on exertion in the absence of dyspnea or occurring at rest with emotional stress after meals or during sleep was associated with coronary artery disease in 80% of instances whereas angina occurring only in association with dyspnea on exertion was associated with coronary artery disease in 45% of instances

An important group of aortic valve disease *patients are those with coronary artery disease* who did not have angina pectoris Only two (6 6%) of our 30 patients without chest pain had coronary artery disease The reported incidence of coronary artery disease in the absence of angina pectoris varies widely Graboys and Cohn [3] found 4% of patients with aortic valve disease to have associated coronary artery disease in the absence of angina pectoris Similarly Paquay and coworkers [4] found coronary artery disease in one of 19 patients (5%) and Bonchek and colleag[ues] found no coronary artery disease among [...] patients with aortic valve disease in the absen[ce] of angina pectoris Harris and associates a[nd] Thompson and co workers[15] reported an inci[...] dence of 10% and 13% (respectively) of corona[ry] *artery disease in patients with aortic valve disea[se]* in the absence of angina pectoris Hancock[9] su[g]gested that patients with aortic valve disease a[nd] coronary artery disease in the absence of angi[na] pectoris may present with symptoms of hea[rt] failure This type of patient may be similar [to] those with ischemic cardiomyopathy in t[he] absence of aortic valve disease as described [by] Burch and associates [29] The hemodynamics in t[he] three groups of patients are shown in Table I[...]

The mean pressure gradient across the aort[ic] valve in patients with aortic stenosis tended to [be] lower in patients who also had coronary arte[ry] disease There were no significant differences [in] left ventricular end diastolic pressure in the su[b]groups of patients with aortic stenosis and coro[...]nary artery disease or no coronary artery disea[se] However in the groups with aortic regurgitati[on] and mixed aortic stenosis aortic regurgitation t[he] left ventricular end diastolic pressure was high[...] in the subgroups of patients with associat[ed] coronary artery disease There were no significa[nt] differences in the cardiac index between the d[if]ferent groups of patients

Comparing the ejection fraction in patie[nts] with coronary artery disease in the differe[nt] groups we found significantly higher ejecti[on] fractions in patients with aortic stenosis rath[er] than in patients with aortic regurgitati[on] ($\underline{P} = 0\,001$) or mixed aortic stenosis aortic reg[ur]gitation ($\underline{P} = 0\,05$) There was no significant d[if]ference in ejection fraction between the aor[tic] regurgitation group and the mixed aortic steno[sis] aortic regurgitation group There was also [...] significant difference in the ejection fraction [...] the patients without coronary artery disea[se] between the different groups

Calcification of the aortic valve was much mo[re] common in the groups with aortic stenosis a[nd] mixed aortic stenosis aortic regurgitation Dy[sp]nea on exertion (Class III or IV New York Hea[rt] Association) was much more common in patie[nts] with mixed aortic stenosis aortic regurgitatio[n] Syncope was present in the coronary artery d[is]ease and no coronary artery disease subgroups [...] patients with aortic stenosis however it occurr[...]

dient across the aortic valve was 65 ± 23.8 mm Hg, the aortic valve area was 0.27 ± 0.07 cm / M², the left ventricular end-diastolic pressure was 34 ± 10.3 mm Hg, the cardiac index was 2.1 ± 0.6 L/min/M², and the left ventricular ejection fraction was 50 ± 13%. In the subgroup without coronary artery disease, the mean systolic pressure gradient across the aortic valve was 67 ± 24 mm Hg. The left ventricular end-diastolic pressure was 22 ± 13 mm Hg, the cardiac index was 2.4 ± 0.4 L/min/M, and the left ventricular ejection fraction was 57 ± 19%.

Discussion

Angina pectoris is a well recognized symptom of patients with significant aortic valve disease in the absence of coronary artery disease. The mechanisms responsible for angina pectoris in aortic valve disease can be explained on the basis of an imbalance between myocardial oxygen supply and demand.[1, 3, 19, 22] Fallen and associates demonstrated that patients with severe aortic stenosis but no demonstrable obstructive coronary artery disease have relatively fixed coronary flow response to catecholamine administration stress, resulting in abnormal myocardial metabolism and ischemia. A fixed coronary flow and decreased myocardial oxygen supply result from the fixed stenotic valve orifice and the low mean aortic pressure.

Other factors that may cause decreased oxygen supply to the myocardium in patients with aortic stenosis are the prolonged ejection time, which, if combined with the tachycardia of exercise, results in a decreased diastolic filling period, the increased left ventricular wall tension,[7, 3] the increased left ventricular mass, and the abnormal flow patterns in the aortic root.[2] Increased myocardial oxygen demand may result from myocardial hypertrophy and increased wall tension due to elevated left ventricular end-diastolic pressure. In patients with aortic regurgitation, angina may be due to an increase in wall tension secondary to increased left ventricular volume and to the lower coronary perfusion pressure during diastole. The presence of significant coronary artery disease in patients with aortic valve disease is an additional, critically important single factor causing angina pectoris.

There is wide variation in the reported prevalence of angina pectoris in patients with significant aortic valvular disease, ranging from 40 to 80% for predominant aortic stenosis[5] and 3 to 30% for predominant aortic regurgitation.[24] Similarly, the prevalence of coronary artery disease in aortic valve disease has been reported to be within a wide range between 20 and 63%.[10, 13, 4, 8] This wide variation in the prevalence of angina and coronary artery disease in patients with aortic valve disease may be a result of differences in the ages of the patients studied and the variable criteria used by different investigators in defining significant coronary artery stenosis. Some authors[1, 13, 2, 2] have used a criterion for significant stenosis lumen narrowing of at least 70 to 75%, but others[14, 3] have used as significant lumen narrowing of ≥ 50%. There is general agreement that in patients without aortic valve disease a lumen narrowing of 70 to 75% is probably needed to cause reduction of coronary flow; however, we agree with Hancock,[8] with Linhart and colleagues,[4] and with Moraski and associates that in patients with significant aortic valve disease a lumen narrowing of ≳ 50% can cause significant hemodynamic abnormalities in the coronary circulation.

The rate of chest pain in our total group of 90 patients was 66%, whereas the rate of coronary artery disease in the same group was only 39%. This indicates that chest pain is not related to coronary artery disease in more than half of the patients with aortic valve disease. However, when aortic valve disease was associated with coronary artery disease, the rate of chest pain was 94%.

The higher incidence of chest pain in patients with aortic valve disease and associated coronary artery disease as compared with patients without coronary artery disease is expected, since both diseases have an additive effect upon ischemia. Of the 55 patients with aortic valve disease but no associated coronary artery disease, eight patients (16%) had typical angina pectoris, 19 patients (35%) had atypical chest pain, and 28 patients (49%) had no chest pain.

The distribution of coronary artery disease in the three groups of patients was 46% in predominant aortic stenosis, 35% in severe aortic regurgitation, and 30% in the mixed aortic stenosis-aortic regurgitation group. Although the rate of coronary artery disease in predominant aortic stenosis was higher than in the aortic regurgitation or mixed aortic stenosis-aortic regurgitation groups, the difference was not statistically significant.

The group with predominant aortic stenosis had more severe disease involving multiple vessels and included three patients with left main

Site of origin of ventricular premature beats in patients with mitral valve prolapse

Edgar Lichstein M D F A C C
Brooklyn N Y

Mitral valve prolapse is a common abnormality,[1] and is frequently associated with ventricular premature beats (VPB) Although malignant ventricular arrhythmia and sudden death are rare [3] they have been reported[4] and are a cause for concern Many features of VPBs have been analyzed in an attempt to predict which may have malignant characteristics and a poor prognosis The site of origin of a VPB is thought to correlate with underlying cardiac pathology and perhaps with prognosis

This study examines the vectorcardiogram of VPBs in ten patients with mitral valve prolapse These VCG loops were then used to postulate the site of origin and attempt to relate this with the type of prolapse and the possible etiology of the VPB

Methods

The study population consisted of 10 patients with mitral valve prolapse diagnosed in our Echocardiographic Laboratory There were two males and eight females with a mean age of 29 1 ± 11 1 years All patients had a midsystolic click and a mid or late systolic murmur Although some of the patients had atypical chest pain none had typical clinical features or ECG evidence of coronary heart disease Three patients had complete cardiac catheterization which confirmed the presence of mitral valve prolapse and the absence of coronary artery disease

Echocardiograms were performed on a Unirad 100 series Echoscope Standard scanning techniques were used

Vectorcardiograms (VCGs) were performed on an Instruments for Cardiac Research Model VCG 1V Vectorcardiograph This system allows the vector loop to be interrupted 400 times per second The Frank Lead System was used for vectorcardiograms of both the normal QRS and the ventricular premature beat All 10 patients were having unifocal ventricular premature beats After the vector of the normal QRS was recorded, the patients were monitored through the VCG unit until a ventricular premature beat occurred The ventricular premature beat was stored in the machine s memory and then all three vector loops were inscribed from the same ectopic beat

Results

The direction of the mean vector of the ventricular premature beat in both the frontal and horizontal plane for all 10 patients is shown graphically in Fig 1 The rotations of the vector loops the type of mitral valve prolapse and the proposed site of origin of the ventricular premature beat are shown in Table I

Fig 2 shows the standard 12 lead electrocardiogram from patient No 9 This 16 year old female presented because of palpitation and was found to have a typical midsystolic click and midsystolic murmur The electrocardiogram shows sinus rhythm with ventricular premature beats and is otherwise within normal limits Fig 3 shows this patient s echocardiogram demonstrating prolapse of the posterior leaflet of the mitral valve Fig 4 shows the vectorcardiogram performed on this patient s ventricular premature beat

Discussion

Mitral valve prolapse is a common abnormality especially in the younger population Auscula

only in patients without coronary artery disease in both groups of aortic regurgitation and mixed aortic stenosis aortic regurgitation This is a surprising finding but it should be interpreted with caution since the number of patients under analysis was small

There was electrocardiographic evidence of myocardial infarction present in two patients with and in two patients without coronary artery disease in the group with aortic stenosis Myocardial infarction which is rare in the absence of obstructive coronary artery disease was reported to occur in patients with aortic stenosis[1] as well as in patients without aortic valve disease and in patients with hypertrophic cardiomyopathy [2]

The etiology of myocardial infarction in patients with aortic stenosis but without significant atherosclerosis is unclear The possible causes are calcific embolus the fact that the increased cardiac mass may have been too great for the existent coronary blood supply narrowing of the intramural coronary arteries and brief periods of hypoxia due to transient hypotension Recently it was shown that myocardial infarction may be precipitated by coronary spasm in vessels with or without atherosclerosis[13] There was no statistical difference in the presence of one or more risk factors for coronary artery disease in the different groups of patients

Our study suggests that although patients with aortic valve disease and typical angina pectoris are most likely to have associated coronary artery disease it is not possible to accurately predict this condition by clinical or hemodynamic findings The absence of chest pain excluded associated coronary artery disease in 94% of our patients with aortic valve disease These findings are in some agreement with the findings of several other investigators [25, 2] but considerably different from the findings of others [8, 1, 15, 24] This raises the question once again whether coronary arteriography should be performed routinely in every patient with aortic valve disease undergoing evaluation with cardiac catheterization Linhart and colleagues[14] suggested that coronary arteriography should be performed in all patients undergoing evaluation for aortic valve replacement since they found significant coronary artery disease in 25% of their patients who had no angina pectoris There is general agreement that coronary arteriography should be performed in all patients with angina pectoris when they are evaluated for aortic valve disease The information provided by coronary arteriography may prove to be important with regard to operative risk and long term prognosis when performing coronary bypass at the time of aortic valve surgery[9] There is however disagreement as to whether coronary arteriography should be performed in patients with aortic valve disease without angina pectoris

Some investigators do not recommend routine coronary arteriography in patients with aortic valve disease who do not have angina pectoris [11] This negative recommendation is based on the observation that none of their patients or those reported by others [4, 7] without angina had significant coronary artery disease Other investigators disagree with this point of view and recommend routine coronary arteriography in all patients with aortic valve disease undergoing cardiac catheterization [15, 5] Their reasoning is that patients with aortic valve disease who are free of angina pectoris have a definite albeit small risk of concomitant significant coronary artery disease

Since the combination of aortic valve replacement and coronary bypass surgery seems to lower the risk of operative morbidity and mortality in aortic valve replacement and improves the long term prognosis we agree with those who advocate routine coronary arteriography for all patients over the age of 40 even if they do not have angina pectoris Another reason for routine coronary arteriography in patients studied for aortic valve replacement is to rule out anomalous aortic origin of coronary arteries These anomalies occur in 0 6 to 1 2% of the total patients undergoing coronary arteriography and are more common in patients with valvular disease[3] Knowing the presence of anomalous origin or the course of a coronary artery may avoid injury to the vessel during aortic valve replacement or may exclude the anomalous vessel from perfusion if this technique is used to perfuse the myocardium during extracorporeal circulation

Summary

We studied the clinical hemodynamic and angiographic findings of 90 consecutive patients with significant symptomatic aortic valve disease 40 years of age or older to evaluate the prevalence of angina pectoris in relation to coronary artery disease and the effect upon cardiac function

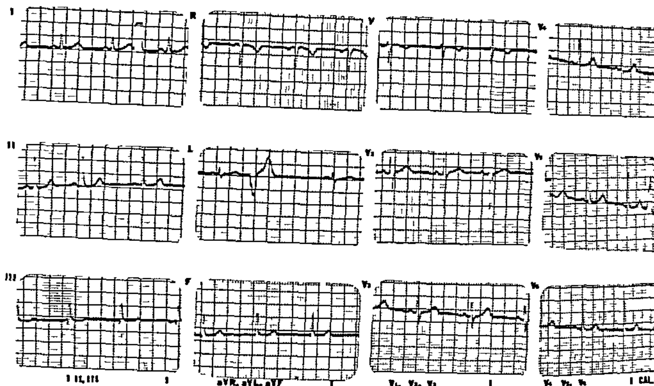

Fig 2 Standard 12 lead electrocardiogram recorded on patient No 9 The rhythm is normal sinus with an occasional ventricular premature beat The QRS morphology is within normal limits

lapse both using Holter monitoring and exercise testing Despite this apparent cause and effect relationship Shappel and Marshall[4] have reported two patients with sudden death and mitral valve prolapse who showed no documented arrhythmia despite extensive ECG and maximum exercise testing Lichtman and co workers[14] have noted a high prevalence of sinus bradycardia and sinus arrest and suggest that this might be one possible mechanism for sudden death

Since most investigators do feel that there is some relationship between verticular arrhythmia and sudden death the mechanism of ventricular irritability becomes important in planning preventive therapy Criley and colleagues[15] postulated that during systole the mitral leaflets become progressively inflated and thus are exposed to an abnormal stress as they balloon into the left atrium tugging on the chordae and papillary muscles During early diastole the leaflets now above the level of the mitral annulus abruptly dump the blood contained within their ventricular aspect into the base of the left ventricle This impact may produce a mechanical stimulus for producing a ventricular ectopic beat This hypothesis however does not account for the intermittent nature of this arrhythmia Micro electrode studies in monkeys and dogs have fou that muscle fibers situated in the mitral val leaflet are capable of developing spontaneo diastolic depolarization resulting in automat impulse initiation when stretched or exposed epinephrine[16, 17] Muscle bundles with accor panying muscular vessels are known to en normally in the mitral leaflet of man[18] Therefor in addition to possible mechanical stimulation the myocardium by excessive movement of th mitral valve leaflet a functional anatomic bas for arrhythmias associated with mitral valve pro lapse syndrome may be ectopic impulse initiatio that occurs in the valve leaflet muscle bun dles[19]

At the present time antiarrhythmic therapy i suggested only when the patient is bothered b palpitations or when malignant characteristics o VPBs are noted Therapy is usually limited t oral propranolol but may occasionally requir diphenylhydantoin when a prolonged QT interval is noted Propranolol may be the drug of choice since in addition to its intrinsic antiarrhythmic action it decreases left ventricular contractility increases left ventricular volume and therefore may lessen myocardial ischemia resulting from excessive traction on the papillary muscle[20] A

tory and echocardiographic features of mitral prolapse may be seen in asymptomatic populations with an incidence ranging from 6 3% to nearly 18% One of the major clinical concerns with this abnormality is the high incidence of ventricular arrhythmia and the occasional occurrence of sudden death

It is thought that there is some relationship between sudden death and the previous occurrence of ventricular premature beats Winkle and associates studied seven patients with prolapse who survived one or more episodes of life threatening ventricular arrhythmias VPBs were present in the ECG of six of the seven and were frequent during exercise testing and Holter monitoring Wei and colleagues[6] described 10 patients with mitral valve prolapse among a larger group of patients with refractory ventricular arrhythmia Four of these patients with prolapse had a history of cardiac arrest due to ventricular fibrillation Other investigators[3, 11] have noted frequent VPBs in patients with mirtal valve pro

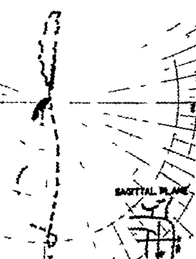

Fig 4 Vectorcardiogram of a ventricular premature beat recorded in patient No 9 The vector loop is interrupted 400 times per second.

superiorly in the frontal plane are thought to arise from the posterior wall of the left ventricle and those that are directed inferiorly arise from the anterior wall of the left ventricle VPBs arising from the base of the left ventricle would have forces directed anteriorly inferiorly and to the left They would be superior or inferior depending on whether the VPB arises from the posterior or anterior wall. Beats arising from the apex of the left ventricle would be directed posteriorly superiorly and to the right All beats originating in the right ventricle had a left bundle pattern The majority were directed inferiorly and to the right Rosenbaum felt that they arose from the anterior wall of the right ventricle and not from the septum They originate in the myocardium and not the Purkinje tissue since the inscription of the initial part of the QRS is slow He felt that they may arise from the anterior papillary muscle of the right ventricle and that perhaps the stretching of that structure during normal mechanical activity of the ventricle could trigger ventricular premature beats.

Using this type of classification Hiss and colleagues[8] evaluated VPBs in a population of healthy male subjects of various ages They found that the number of VPBs from the right ventricle were approximately three times as great as those from the left The incidence of VPBs from the right ventricle increased fourfold from the youngest to the oldest age group (20 to 45+ years) while the rate for those originating in the left ventricle did not change significantly

If one accepts this type of classification for the purpose of determining origin then the significance of this site of origin must be examined. The coronary drug project data showed an increased mortality rate in patients with VPBs following myocardial infarction However these investigations found that this excess risk was associated

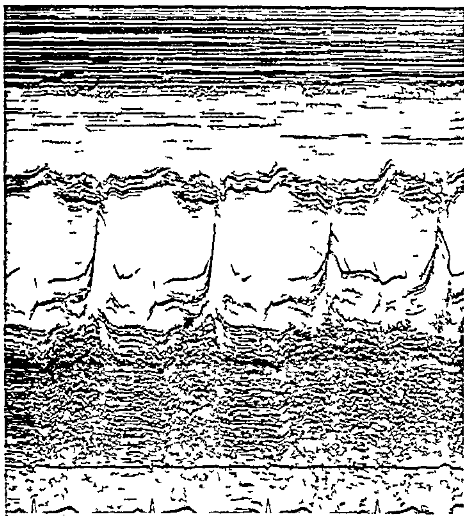

Fig 3 Echocardiogram recorded on patient No 9 *The arrow* indicates late systolic prolapse of the posterior leaflet of the mitral valve

radical and seldom used method of therapy is mitral valve replacement which occasionally has been thought to be necessary for the prevention of recurring life threatening arrhythmia [21] More recently aprindine has been used Troup and Zipes [2] describe the use of this drug in seven patients with symptomatic potentially life threatening ventricular arrhythmias Conventional antiarrhythmic drugs had been tried and were unsuccessful Aprindine resulted in a greater than 91% reduction in the number of VPBs in 24 hours in addition to a marked reduction in the frequency and duration of ventricular tachycardia

VPBs may be found in all age groups even in the absence of cardiac disease Since they are so common many have attempted to find characteristics which differentiate benign from malignant VPBs Rosenbaum using electrocardiograms from humans has classified ventricular extrasystoles according to their form and their site of origin Mautner and Girotti [4] arrived at a similar classification using pacemaker induced ventricular beats in the experimental dog It becomes apparent from these studies that one cannot simply identify the site of origin by merely noting the presence of a classical right bundle or left bundle pattern in the frontal plane Manning and colleagues[25] have noted a common discordance between the findings in the limb and the precordial leads Because of this a determination must be made by seeing the same VPB in both the frontal and horizontal plane or by the use of the vectorcardiogram Rosenbaum s classification[21] states that VPBs from the left ventricle will have a right bundle pattern Those that are directed

tissue judged by the slow initial forces (3) There was no relationship between the location of prolapse and the VPB morphology

Summary

This study examines the site of origin and possible etiology of ventricular premature beats (VPB) in patients with mitral valve prolapse

Ten patients with mitral valve prolapse documented by echocardiogram form the study group All patients had prolapse of the posterior leaflet and three additionally had anterior prolapse There were eight females and two males, with a mean age of 29 1 ± 11 1 years All patients were having unifocal VPBs at rest A vectorcardiogram (VCG) was taken of the VPB by a technique which allowed all VCG loops to be written from the same beat

The VCG analysis indicated that the VPB forces were directed anteriorly inferiorly and to the left in six patients In two patients the VPB was directed posteriorly inferiorly and to the left consistent with right ventricular origin One of these patients had episodes of ventricular tachycardia One was anterior superior and to the left, and one was markedly anterior superior and to the right In all patients the initial portion of the QRS was inscribed slowly The three patients with additional anterior prolapse did not show a common difference from those with isolated posterior prolapse

It is concluded that (1) The majority of these VPBs originate from the posteriorbasal portion of the left ventricle (2) They originate in the myocardium and not in the Purkinje tissue (3) There is no relationship between the location of prolapse and the VPB morphology

I wish to thank Ms Carol Scott for her assistance in preparing the manuscript and Dr Prem K. Gupta for performing the echocardiograms

with frequency of VPBs but was independent of ECG criteria such as whether the VPBs originated in the right or left ventricle Lewis and associates[28] studied 165 patients with VPBs classified as either of right or left ventricular origin Patients with no heart disease had a higher incidence of right ventricular VPBs Of 102 patients with left ventricular disease 51% had left ventricular VPBs Of the six patients with right ventricular disease five of six (83%) had right ventricular VPBs These authors concluded that patients with right ventricular disease generally had right ventricular VPBs In patients with left ventricular disease the incidence of left ventricular and both right and left ventricular VPBs was much higher than in patients with right ventricular disease alone Kennedy and Underhill studied 25 asymptomatic healthy patients because of frequent or complex VPBs These beats were classified by ECG and in 10 vector criteria were also used The beats were predominantly of right ventricular origin in 19 of 25 subjects and disappeared during exercise in 21 of 23 subjects Three of the 10 subjects classified by vector criteria had beats which were thought to originate in the left ventricle but were still thought to be benign Pietras and colleagues[30] studied 27 patients with chronic recurrent ventricular tachycardia Fifteen had left ventricular tachycardia and all had organic heart disease There were 12 with right ventricular tachycardia and they were younger mostly female and only three had organic heart disease During follow up there were three deaths and these were all in the group with left ventricular tachycardia These authors mention that one patient had a pansystolic murmur but they do not document the diagnosis of mitral prolapse in any of these patients It is of interest to note that one of our patients (patient No 3) had ventricular tachycardia during an exercise test which required DC cardioversion This patient s VPBs and his ventricular tachycardia were both consistent with right ventricular origin

Because of this proposed relationship between the site of origin and the presence of disease removal of disease such as left ventricular aneurysm has been suggested for recurrent ventricular tachycardia While this may be successful [31] it is also reported that patients with right ventricular tachycardia may also improve after left ventricular aneurysmectomy [3] Tomisawa and co workers[33] described one patient with right ventricular tachycardia which was abolished by right ventricular aneurysmectomy and Engle and associates[5] describe two children with left ventricular tachycardia which was abolished by excision of a left ventricular tumor With the exception of the rare patients with right ventricular tachycardia and left ventricular aneurysmectomy these data are though to validate the proposed ECG localization of ventricular tachycardia [30] Bodenheimer and colleagues[3] studied 39 patients with VPBs who had cardiac catheterization Nineteen had left ventricular VPBs 17 had right ventricular VPBs and three had both left and right ventricular VPBs Of the 19 with left ventricular VPBs 15 had coronary disease and four were normal Of the 17 with right ventricular VPBs 11 had coronary disease and six were normal The three patients with both left and right VPBs also had coronary disease These findings indicate that in patients with chest discomfort syndrome there was no relationship between site of origin of the VPB and either the prevalence or the severity of coronary disease These authors note that the Purkinje fibers penetrate the interventricular septum for a considerable distance from the left ventricle towards the right ventricle Thus an impulse originating from the left ventricular portion of the septum could depolarize the right ventricle first These authors suggested that this might explain the presence of right ventricular VPBs in three patients with isolated disease of the left anterior descending coronary artery

We classified the origin of VPBs using vector cardiographic criteria suggested by Sano and co workers Using these criteria it was felt that only two patients had VPBs originating in the right ventricle and the remaining eight had VPBs originating in the left ventricle The most common site of origin was the posteriorbasal portion of the left ventricle This is perhaps consistent with the hypothesis that mechanical irritation produced by the billowing valves dumping blood into the left ventricle could be the cause of this arrhythmia A possible origin from the base of the papillary muscles seems unlikely, since that origin would have been expected to produce a superiorly oriented electrical force while ours were mostly inferiorly directed

From this study we conclude that (1) The majority of these VPBs originate from the posteriorbasal portion of the left ventricle (2) They originate in the myocardium and not the Purkinje

Cardiovascular manifestations of tricyclic antidepressant overdose

Rene A Langou M D
Craig Van Dyke M D
Steven R Tahan M D
Lawrence S Cohen M D
New Haven Conn

Cardiotoxicity in tricyclic overdosage has been reported frequently during the last 15 years Most studies[1] have focused attention on the characteristic pattern of electrocardiographic disturbances which as Giles pointed out is so constantly seen as to be pathognomonic Little clinical information however regarding the broader aspects of the effects of tricyclic overdose upon the cardiovascular system has been accumulated

We have recently reported on clinical findings of patients with tricyclic antidepressant (TCA) overdoses and their correlations with (TCA) plasma levels Our present study will concentrate only on the cardiovascular manifestations of TCA overdose We present the results of a retrospective analysis of the cardiac manifestations of 35 cases of TCA overdosage 23 cases with amitriptyline and 12 cases with imipramine

Materials and methods

The clinical histories of 23 cases of amitriptyline overdose and 12 cases of imipramine overdosage admitted to Yale New Haven Hospital from January 1973 to December 1978 were reviewed The criteria for inclusion in this study were history of tricyclic antidepressant overdose and elevated plasma levels of TCA [9] Patients who were known to have ingested significant amounts of drugs other than TCA were excluded from the study

The patients ranged in age from 13 to 73 years eight patients were teenagers Twenty seven patients were female and eight patients were male There was no previous history of cardiac disease in any case Twenty patients were receiving TCA drugs chronically

The clinical protocol followed in each one of the 35 patients after admission to the intensive care unit at Yale New Haven Hospital was physical examination routine laboratory and toxicologic determinations electrocardiograms and routine chest x rays In five patients right sided heart pressures and cardiac output by thermodilution technique were sequentially measured through a Swan Ganz catheter placed in the pulmonary circulation using standard techniques [10] In addition determination of plasma levels of TCA and their respective active metabolites were obtained Initial blood samples for tricyclic levels were obtained within 2 to 4 hours after admission to the intensive care unit In addition levels were determined at variable intervals thereafter Plasma concentrations of the parent compounds amitriptyline and imipramine and their respective pharmacologically active metabolites nortriptyline and desmethylimipramine were measured by gas liquid chromatography using a nitrogen sensitive detector accord

sions of normal saline solution (1 5 ± 0 7 liters) in an average of 3 hours After fluid infusion the following hemodynamic measurements were obtained—heart rate 118 ± 12 beats per minute pulmonary capillary wedge pressure 12 ± 3 mm Hg mean pulmonary artery pressure 18 ± 6 mm Hg systemic systolic blood pressure 82 ± 12 mm Hg and cardiac output 4 8 ± 0 5 mm Hg After fluid infusion in these five patients right sided and left ventricular filling pressures were normalized and cardiac output was significantly increased A small but statistically significant rise in systolic blood pressure was also observed However no change in heart rate was noted after the therapeutic intervention The systemic hypotension was finally corrected in these five particular patients with the infusion of sympathomimetic amines Of note is that the heart rate remained elevated despite complete correction of all measured hemodynamic parameters (118 ± 10 beats/minute)

Electrocardiographic manifestations on admission Of the 35 patients with amitriptyline or imipramine overdose sinus tachycardia was documented in 71% (25 of 35) supraventricular tachycardia was found in 6% (two of 35), premature ventricular beats were seen in 34% (12 of 35) prolongation of the PR interval (first degree A V block) was documented in 11% (four of 35) Widening of the QRS complex was observed in 29% (10 of 35) Of these patients with a widened QRS complex five patients had right bundle branch block and five patients had non specific intraventricular conduction delay Abnormal ST segments and T waves were present in 28% (10 of 35) and prolongation of the QT interval was apparent in 86% (30 of 35) (Table II) Seven of the 35 patients had completely normal electrocardiograms

Twelve patients demonstrated severe ventricular ectopy (more than 60 PVC s per hour) in the 12 lead admission electrocardiograms An additional patient developed severe ventricular ectopy upon arrival at the intensive care unit Of these 13 patients 10 patients had uniform PVCs No patients had sustained repetitive ventricular tachyarrhythmias Three of the original 13 patients with severe ventricular ectopy were reported as having a cardiopulmonary arrest prior to admission

The duration of ventricular ectopic activity ranged up to 72 hours after admission but 10 patients did not show any further ventricular ectopy after 36 hours Intravenous infusion of lidocaine (2 0 ± 0 5 mg/minute mean ± SD) was used to control the frequent premature ventricular beats in all 13 patients The use of this antiarrhythmic agent did not produce any detectable undesirable rhythm disturbances After transfer from the intensive care unit to regular medical wards none of these patients were found to have arrhythmias Long term Holter monitor tracings were obtained in all of these patients Only one had severe ventricular ectopy (multiform premature ventricular beats) in the first Holter monitor tracing (72 hours after admission) which disappeared in the second Holter monitor recording (before discharge) Two patients had nonsevere ventricular ectopy in the first Holter monitor recording which also disappeared at the time of discharge (second Holter monitor recording) No arrhythmias were noted in the Holter tracings of the remaining ten patients

Evolution of abnormal electrocardiographic manifestations Twenty eight patients with abnormal admission electrocardiograms had the following electrocardiographic evolution during their hospital stays Sixteen patients (including five with widened QRS complexes) had their electrocardiogram revert to normal within [illegible] hours after admission The remaining 12 patients demonstrated persistent prolongation of the QT interval at 72 hours following admission

Fig 1 presents the relationship between the duration of the QRS complex and plasma level of imipramine in four patients with widened QRS complexes in which sequential TCA blood levels were available There was a

ing to methods previously reported from our institution [1,2]

The electrocardiographic interpretations were made according to the Minnesota Code[13] for rhythm AV conduction QRS complex and ST and T waves The QT interval was corrected for rate according to the formula of Ashman and associates[14] Electrocardiograms were obtained upon admission to the intensive care unit and thereafter daily until tracings were interpreted to be within normal limits Twenty four hour ambulatory long term electrocardiograms (Holter monitor) were obtained in patients who had ventricular ectopy on admission at 72 to 96 hours after admission and the day before discharge from the hospital (5 to 7 days after admission) The scanning of the Holter monitor tapes was done by a highly trained physician and was reviewed by the staff cardiologist Initially each Holter monitor tape was reviewed at fast speed (60 times real time) using a commercially available scanner When any abnormal rhythm was identified the Holter monitor tape was replayed and the electrocardiogram was recorded in paper at a speed of 25 mm/sec The abnormal rhythm was classified and the number of ectopic beats were manually counted Cardiac arrhythmias were classified as supraventricular tachyarrhythmias ventricular tachyarrhythmias and conduction disturbances Supraventricular tachyarrhythmias were classified as atrial premature beats (>60/hour) atrial flutter and atrial fibrillation Ventricular tachyarrhythmias were classed as (1) severe ventricular ectopy (either premature ventricular contractions (PVC) >60/hour multiform premature ventricular contractions repetitive PVC s or ventricular tachycardia or fibrillation) and (2) nonsevere ventricular ectopy (uniform PVCs at <60/hour) Conduction disturbances were recorded as atrioventricular block and intraventricular block

The medical treatment in this series of 35 patients with tricyclic overdose was supportive only and included intravenous fluids sympathomimetic amines gastric lavage activated charcoal magnesium citrate and support of respiration Hemodialysis and peritoneal dialysis were not used in these patients and all recovered uneventfully

Plasma levels The total initial plasma levels of amitriptyline plus active metabolites ranged from 180 to 1 560 ng/ml with a mean ± SD of 430 ± 74 ng/ml and plasma levels of imipramine plus active metabolites ranged from 150 to 1 732 ng/ml with a mean ± SD of 665 ± 137 ng/ml

Statistical analysis When appropriate the data were statistically analyzed by unpaired Student t test A p value less than 0 05 was considered as statistically significant

Results

Physical findings The admission clinical findings in the 35 patients with TCA overdose are displayed in Table I Tachycardia (heart rate >110 beats per minute [bpm]) was present in 71% of patients (25 of 35) hypotension (systolic blood pressure <80 mm Hg) was seen in 51% (18 of 35) hypotension occurred more often with amitriptyline overdose (65% 15 of 23) than with imipramine overdose (16% 2 of 12)

Cardiovascular hemodynamic measurements In five patients with marked hypotension and tachycardia a Swan Ganz catheter was placed in the pulmonary artery Heart rate pulmonary capillary and pulmonary artery pressures systemic arterial pressure and cardiac output were sequentially measured These measurements were repeated as clinically indicated during a 24 hour period The initial hemodynamic measurements were heart rate 121 ± 8 beats per minute (mean ± SD) pulmonary capillary wedge pressure 6 ± 3 mm Hg mean pulmonary artery pressure 10 ± 4 mm Hg systemic systolic blood pressure 65 ± 8 mm Hg and cardiac output 2 8 ± 1 2 liters/minute The initial low left ventricular filling pressures (pulmonary capillary wedge pressures) were corrected with infu

sions of normal saline solution (1 5 ± 0 7 liters) in an average of 3 hours After fluid infusion the following hemodynamic measurements were obtained—heart rate 118 ± 12 beats per minute pulmonary capillary wedge pressure 12 ± 3 mm Hg mean pulmonary artery pressure 18 ± 6 mm Hg systemic systolic blood pressure 82 ± 12 mm Hg and cardiac output 4 8 ± 0 5 mm Hg After fluid infusion in these five patients right sided and left ventricular filling pressures were normalized and cardiac output was significantly increased A small but statistically significant rise in systolic blood pressure was also observed However no change in heart rate was noted after the therapeutic intervention The systemic hypotension was finally corrected in these five particular patients with the infusion of sympathomimetic amines Of note is that the heart rate remained elevated despite complete correction of all measured hemodynamic parameters (118 ± 10 beats/minute)

Electrocardiographic manifestations on admission Of the 35 patients with amitriptyline or imipramine overdose sinus tachycardia was documented in 71% (25 of 35) supraventricular tachycardia was found in 6% (two of 35), premature ventricular beats were seen in 34% (12 of 35) prolongation of the PR interval (first degree A V block) was documented in 11% (four of 35) Widening of the QRS complex was observed in 29% (10 of 35) Of these patients with a widened QRS complex five patients had right bundle branch block and five patients had non specific intraventricular conduction delay Abnormal ST segments and T waves were present in 28% (10 of 35) and prolongation of the QT interval was apparent in 86% (30 of 35) (Table II) Seven of the 35 patients had completely normal electrocardiograms

Twelve patients demonstrated severe ventricular ectopy (more than 60 PVC s per hour) in the 12 lead admission electrocardiograms An additional patient developed severe ventricular ectopy upon arrival at the intensive care unit Of these 13 patients 10 patients had uniform PVCs. No patients had sustained repetitive ventricular tachyarrhythmias Three of the original 13 patients with severe ventricular ectopy were reported as having a cardiopulmonary arrest pri to admission

The duration of ventricular ectopic activi ranged up to 72 hours after admission but patients did not show any further ventricul ectopy after 36 hours Intravenous infusion lidocaine (2 0 ± 0 5 mg /minute mean ± S was used to control the frequent premature ve tricular beats in all 13 patients The use of tl antiarrhythmic agent did not produce any dete able undesirable rhythm disturbances. Af transfer from the intensive care unit to regu medical wards none of these patients were fou to have arrhythmias Long term Holter monit tracings were obtained in all of these patien Only one had severe ventricular ectopy (mul form premature ventricular beats) in the fi Holter monitor tracing (72 hours after adm sion) which disappeared in the second Holt monitor recording (before discharge) Two p tients had nonsevere ventricular ectopy in t first Holter monitor recording which also disa peared at the time of discharge (second Holt monitor recording) No arrhythmias were not in the Holter tracings of the remaining t patients

Evolution of abnormal electrocardiograph manifestations Twenty eight patients with a normal admission electrocardiograms had the f lowing electrocardiographic evolution dur their hospital stays Sixteen patients (includi five with widened QRS complexes) had th electrocardiogram revert to normal within hours after admission The remaining 12 patien demonstrated persistent prolongation of the Q interval at 72 hours following admission

Fig 1 presents the relationship between t duration of the QRS complex and plasma level imipramine overdose in four patients wi widened QRS complexes in which sequenti TCA blood levels were available There was

progressive normalization of the QRS complex duration while the plasma levels of imipramine were *falling to lower levels The QRS complex* durations were in the normal range when the plasma level of imipramine was below 200 ng/ml

Discussion

The pharmacology of TCA on the cardiovascular system has been extensively studied [13] These drugs have a number of pharmacological actions that include anticholinergic activity direct myocardial depressant activity and a sympathomimetic activity which is related to their ability to block the reuptake of adrenergic amines All of these actions may contribute to the adverse effects of TCA on the cardiovascular system however the individual dose response curves for each of these actions remains undefined A factor further influencing TCA cardiotoxicity is that these drugs are highly concentrated by the myocardium [1]

Cardiovascular findings in TCA overdose The most common cardiovascular signs of TCA overdose in this study were tachycardia (71% 25 of 35 patients) and hypotension (51% 18 of 35 patients) Previous studies [9,1] of therapeutic and/or toxic doses of TCA have demonstrated that tachycardia is a prominent feature This chronotropic effect could be related to several physiologic mechanisms direct stimulation of the sinus node reflex mechanism induced by the clinically significant hypotension or direct effect upon the cardioregulatory center in the central nervous system The tachycardia observed in our patients appeared to be independent of changes in blood pressure The five patients who were invasively instrumented demonstrated no change in heart rate when the blood pressure was restored to normal levels This finding suggested that the tachycardia *cannot be explained by a hypotension* reflex mechanism alone By this study we were not able however to elucidate the operative pathophysiologic mechanism

Hypotension was the second most prominent cardiovascular manifestation of TCA overdose occurring in 51% of all cases The first substantial study of TCA on blood pressure reported no change in recumbent blood pressure but there was a significant frequency of postural hypotension These changes were observed especially in older patients and in patients with organic cardiovascular disease Subsequent studies [3] documented that postural hypotension is independent of age sex and blood levels of TCA The mechanism whereby TCA produces hypotension is unclear [23,6] but it has been attributed to a peripheral effect a myocardial depressant effect a direct effect upon the central nervous system and a combination of these influences

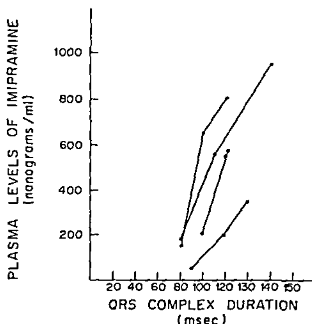

Fig 1 Relationship between plasma levels of imipramine and duration of the QRS complex in four patients with intraventricular conduction defects.

In five hemodynamically monitored patients in our cohort with TCA overdose hypotension was associated with marked intravascular fluid depletion manifested by low left ventricular filling pressures and low cardiac output When left ventricular filling pressures and cardiac output were corrected the blood pressure increased but it still was clinically in the hypotensive range Hemodynamic measurement of cardiac function did not indicate left heart failure These findings suggest a TCA mediated afterload reduction

Thorstrand carefully examined cardiovascular hemodynamics in ten patients who overdosed with TCA using right heart catheterization The hemodynamic data were obtained during and after recovery from coma As judged by the pulmonary arterial diastolic pressure central venous pressure and cardiac output myocardial failure did not occur during overdose in any of these patients

The only other previous attempt to measure

the effects of TCA on left ventricular function in human subjects used systolic time intervals All eight patients in that study had therapeutic levels of TCA An increase in the ratio of pre ejection period over duration of left ventricular ejection time (PEP/LVET) was found in all patients The authors concluded that TCA therapy is associated with a decrement in left ventricular function In interpreting the significance of these results we note that measurements of systolic time intervals may not be adequate to evaluate left ventricular function [29-31]

These two studies have produced contradictory findings on the influence of TCA on left ventricular function The study of Taylor and Braithwaite [8] using therapeutic plasma levels, suggests that these drugs depress left ventricular function Somewhat surprisingly the study of Thorstrand using toxic plasma levels found little effect of TCA on left ventricular function Our findings are in agreement with those of Thorstrand in that TCA at toxic plasma levels did not clinically impair left ventricular function

Electrophysiologic manifestation of TCA overdose The electrophysiologic manifestations of TCA overdose have been reported in detail by several other investigators [3-38] In 1962 Cairncross and Gershon[39] studied imipramine cardiotoxicity in anesthetized cats and dogs These investigators were able to show that increasing doses of intravenous imipramine up to 8 mg/kg produced serious cardiac conduction disturbances which they interpreted as toxic effects on the conduction tissue Boissier and co workers [40] in another experimental study with progressive lethal intoxication in guinea pigs mention that progressively higher degrees of atrioventricular block occurred with increasingly higher doses of TCA and that conduction impairment improved between doses (except when the point of irreversible intoxication occurred when all electrical activity of the heart ceased)

The most characteristic electrocardiographic manifestations found in patients with TCA overdose are conduction and repolarization disturbances atrioventricular block, intraventricular conduction defects T wave changes and prolonged QT interval Tricyclic antidepressants exert a quinidine like action upon the conduction system in all studied species Therefore the toxic manifestations of TCA should be similar to those induced by quinidine toxicity Our study showed a high incidence of conduction impairment in patients with imipramine and amitriptyline overdose prolonged PR interval in 11% prolonged QRS complex in 29% and prolonged QT interval in 86% The pathophysiologic behavior of these conduction disturbances was very similar to that reported in pigs [40]

Of interest is the fact that we did not document ventricular tachycardia in any of our patients, although ventricular tachycardia has been described in the preterminal phase of severe intoxications It is possible that the bizarre wide QRS complexes which are so commonly seen in TCA overdose reflect an aberrantly conducted supraventricular tachycardia rather than ventricular tachycardia Two of our patients, who had a supraventricular tachycardia had very wide and bizarre QRS complexes which reverted to normal when plasma levels of imipramine diminished

It should be noted that no serious ventricular arrhythmia occurred in our patients, and only 13 patients had initial ventricular ectopic activity These ventricular premature beats were treated in the same manner as quinidine-induced ventricular tachyarrhythmias Since the electrophysiologic actions of both quinidine and procainamide are identical to those of TCA it is unlikely that either drug would abolish the ventricular ectopy They may even aggravate the electrophysiologic abnormalities because TCA induced arrhythmias may result from re entrant excitation currents secondary to slowed conduction velocity in the myocardium Lidocaine appears to be the therapeutic drug of choice However abolition of ventricular activity with lidocaine may unmask serious underlying rhythm disorders which might require the placement of a temporary pacemaker In our patients lidocaine infusion was able to control all ventricular ectopic beats without any undesirable effect Thirteen of our patients with initial ventricular ectopy had two (24 hours each) long term Holter monitor recordings only one patient had severe ventricular ectopy and two additional patients had nonsevere ventricular ectopy during the first electrocardiographic recording These three patients were free of ventricular ectopy at the time of the second recording It should be noted that no patients received antiarrhythmic drugs during that late phase of their hospitalization

The relative lack of ventricular arrhythmias in

our cohort was surprising in view of previous reports[13, 36, 3] which suggested a high incidence of malignant arrhythmias with TCA overdose We found no malignant arrhythmias in any of the patients either on admission or during monitoring in the intensive care unit Follow up Holter monitors in 13 of our patients who were felt to be at higher risk showed no ventricular or supraventricular arrhythmias during hospitalization

Clinical implications

This study presented the following relevant clinical cardiovascular information for treating patients with tricyclic antidepressant overdose

1 Tachycardia and hypotension were very frequently found in patients with tricyclic overdose Tachycardia was not solely related to reflex mechanisms induced by systemic hypotension but rather to direct chronotropic effect of tricyclic agents Systemic hypotension was partially related to relative fluid depletion but peripheral vascular mechanisms also played a very important role Cardiac failure was not documented in any of the hemodynamically instrumented patients

2 The most prominent electrophysiologic changes observed appeared to be related to disturbance in conduction and repolarization clinically manifested by AV block intraventricular conduction defects and prolongation of QT interval

3 No malignant rhythm disturbances were seen and the 13 patients with ventricular ectopic activity were successfully treated with lidocaine an antiarrhythmic drug which enhances electrical conduction velocity

Summary

The cardiotoxicity of tricyclic antidepressants (TCA) was studied in 35 patients admitted to Yale New Haven Hospital for an acute overdose 23 patients had amitriptyline overdose and 12 patients had imipramine overdose Twenty seven patients were female and eight were male Their ages ranged from 13 to 73 years Twenty patients were receiving TCA chronically and none had prior cardiovascular disorders Amitriptyline blood levels ranged from 180 to 1 560 ng/ml and imipramine blood levels ranged from 150 to 1 732 ng/ml

Tachycardia occurred in 71% and systemic hypotension occurred in 51% of patients The observed tachycardias were not corrected upon normalization of fluid and blood pressure derangements Systemic hypotension was related to relative intravascular fluid depletion and peripheral vascular dilatation Myocardial failure was not seen clinically or hemodynamically in studied patients

Electrophysiologic manifestations were those of conduction and repolarization abnormalities prolonged PR interval in 11% prolonged QRS complex in 29% and prolonged QT interval in 86% of the patients No malignant ventricular arrhythmias were documented and only 13 patients had ventricular premature beats which were successfully suppressed with lidocaine infusions

All cardiovascular manifestations of TCA overdose disappeared when blood levels of TCA reached therapeutic range Only supportive therapy was utilized in these 35 patients and all patients recovered without complications

We gratefully acknowledge the advice and comments of Dr Allan Goodyer and the secretarial assistance of Mrs. Kathleen Pella and Mrs. Madeline D Agostino

11 Bailey D., and Jatlow P I. Gas-chromatographic analysis for therapeutic concentrations of imipramine and

eter so that it could be placed as near to the ostium of the coronary sinus as possible Coronary sinus blood flow (CSBF) was measured with a continuous dye injection technique using the following formula

$$\text{CSBF (ml /min)} = \frac{Ci - Cp}{Cp} \times f,$$

where *Ci* represents the dye concentration (mg / L) of the injectate *Cp* is the dye concentration of the plateau (mg /L) in the coronary sinus and *f* is the rate of injection (ml /min) The reproducibility of this method had been confirmed by duplicated measurements ($r = 0\,988$ $p < 0\,001$ $n = 18$) and in addition this procedure might make it more practicable to draw a blood specimen from the coronary sinus when compared with the thermister method [9] To confirm whether the blood drawn through the catheter was not contaminated with blood from the right atrium dye was injected into the femoral vein while recording the dye dilution curve from the coronary sinus When any contamination was evidenced by an early appearance of dye the tip of the catheter was further advanced where no reflux appeared from the right atrium The catheter tip and the contamination test were repeatedly checked before and after every stage of the flow measurement and blood sampling The stroke work index (SWI) was calculated from stroke index (SI) and left ventricular pressure using the following formula

$$\text{SWI (g m /M}^2) = \text{SI} \times (\text{LVSP} - \text{LVEDP}) \times \frac{1\,36}{100}$$

where *LVSP* = left ventricular systolic pressure and *LVEDP* = left ventricular end diastolic pressure

The basal hemodynamics were determined at 30 minutes after completing right and left heart catheterizations and 10 ml of blood specimen were withdrawn simultaneously from the coronary sinus and from the aorta for plasma catecholamine assay Then subjects were asked to perform the isometric handgrip exercise (IHG) at 30% of their maximum voluntary contraction for 3 minutes Hemodynamic measurements and blood samplings were repeated during the last minutes of the exercise for each subject

Immediately after the blood specimen was obtained it was transferred into an ice chilled polyethylene tube and plasma was separated by centrifugation at 3,000 r p m for 15 minutes at 4 C Each plasma specimen was preserved wit one tenth volume of 1 0% sodium metabisulfa at −20° C until the assay Plasma catecholamin assay was carried out by our modified procedure of Renzini s original[10, 11] within a fortnight afte blood sampling This method using an exceller fluorescence spectrophotometer (Hitachi Mod MPF 4) installed with a high sensitivity ce assembly (No 018 0050) permitted accura measurement of levels as low as 25 to 50 pg NE/ml of plasma

All statistical analyses were performed by th Student s paired and unpaired t test Mean valu are expressed in terms of the mean ± the sta dard error of the mean

Results

The hemodynamic determinants before a during IHG are shown in Table II Of vario hemodynamic parameters in the resting con tion, cardiac indices lower than 3 00 L/min /M and LVEDP higher than 13 mm Hg were fou in eight and 16 patients, respectively IH induced *significant increase* in heart rate me aortic pressure cardiac output LVEDP SW and CSBF

Plasma catecholamine concentrations in in vidual subjects are tabulated in Table III The was a close correlation between the values norepinephrine in the coronary sinus (NE_{cs}) a those in the artery (NE_A) (Fig 1 *left panel*) T mean value of NE_{cs} in all of the subjects was n significantly different from that of NE_A N significant difference was observed in the levels both NE_{cs} and NE_A among the types of hea diseases However when subjects were divid into two groups according to whether they had higher LVEDP than 13 mm Hg or not NE_{cs} w significantly greater than NE_A in subjects wi normal LVEDP (331 ± 46 and 241 ± 30 pg /m $p < 0\,01$) whereas NE_{cs} did not differ from N in subjects with elevated LVEDP (243 ± 25 a 267 ± 33 pg /ml) The NE_{cs} were also grea than those of NE_A in subjects with normal c diac output more than 3 00 L /min /M (280 ± 33 and 232 ± 22 pg /ml $p < 0\,05$) wh no significant difference was found in oth (295 ± 38 and 318 ± 54 pg /ml)

IHG increased both NE_{cs} and NE_A fro 285 ± 28 to 465 ± 40 pg /ml and from 244 ± to 416 ± 38 pg /ml respectively ($p < 0\,001$) (F

An impaired activity of the cardiac sympathetic nerve may closely participate in the pathophysiological sequence of left ventricular function although its causative or consequential significance remains inconclusive [1] Among a variety of approaches to evaluate sympathetic nerve activity the biochemical evaluations of plasma catecholamines and serum β hydroxylase activity have been proposed as useful means for clinical purposes [3] Currently attention has been directed to measurements of norepinephrine (NE) concentrations in coronary sinus blood as a marker of sympathetic nerve transmitters released from the cardiac tissue [7]

The present paper aims to communicate the simultaneous determinations of plasma catecholamine levels in the coronary sinus and in the aorta in subjects with various cardiovascular disorders and relate them to the functional states of the heart

Methods

Twenty four patients with various cardiovascular diseases and six with functional murmur were involved in this study They consisted of 21 males and nine females ranging in age from 13 to 63 years (mean 35 years) Their clinical descriptions are summarized in Table I None of them had been treated with any sympathomimetic or sympatholytic medication Informed consent was obtained from each subject after the nature and the purpose of the protocol had been explained

Diagnostic cardiac catheterization was performed in these patients without any premedication Left ventricular and aortic pressures were measured through a No 8F Cordis pigtail catheter connected with a Statham P23Db pressure transducer Cardiac output was determined by the indicator dilution method using indocyanine green dye A No 9F Gensini catheter was introduced from the right femoral vein into the coronary sinus for blood sampling and flow measurement The tip of the catheter was confirmed by the injection of contrast media through the cath

parallel rises in NE_{cs} [7] An increased cardiac sympathetic nerve activity induced by exercise has been shown to be associated with an increase in NE_{cs} [7 17] Thus NE_{cs} is expected to reflect directly the sympathetic nerve tone of the left ventricle since the coronary sinus blood is mostly derived from that area However a significant correlation between the values of NE_{cs} and NE_A was observed in the present study as in our previous observation and those made by others [12 17] This may suggest that these values are controlled by the same factors which determine general sympathetic nerve activity It is also possible that NE_{cs} originates not only from cardiac tissue but from other tissue as well In this study the mean individual net uptake of E was about 40% both at rest and during IHG and the remaining amounts of E appeared to pass through the coronary circulation If we assume that a similar percentage of NE escapes from either tissue uptake or metabolic degradation throughout the coronary circulation NE_{cs} levels may be influenced to a considerable degree by levels of NE_A

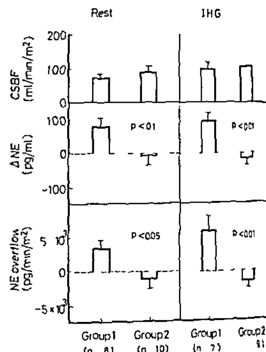

Fig 3 A comparison of coronary sinus blood flow (CSBF), the difference between NE_{cs} and NE_A (ΔNE) and the rate of NE overflow into the coronary sinus between Group 1 with a steep ventricular function curve and Group 2 with a shallow curve These values are expressed as the mean ± the standard error of the mean The mean values of ΔNE during IHG and NE overflow before and during IHG were significantly lower in Group 2 than in Group 1

In the present study both NE_{cs} and NE_A did not differ with regard to the types of heart diseases whereas the resting values of NE_{cs} were significantly greater than those of NE_A in patients with normal LVEDP and/or with normal cardiac output Similar results have been presented in patients undergoing cardiac catheterization [12 15 17] although total catecholamine (NE plus E) levels were lower in the coronary sinus than in the artery [11 14] But it seems noteworthy that this difference could not be observed in patients with elevated LVEDP and/or low cardiac output To further clarify the relationship between NE_{cs} and NE_A in various functional states of the heart we investigated the effect of IHG on both NE_{cs} and NE_A concentrations at

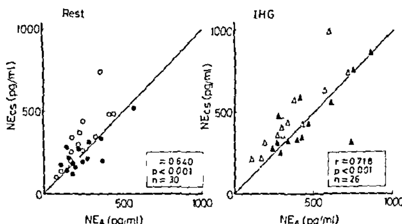

Fig 1 The relationship between NE_{cs} and NE_A at rest and during isometric handgrip exercise (IHG) NE_{cs} significantly correlated with NE_A in both states *The open circles* indicate subjects with normal left ventricular end-diastolic pressure (LVEDP) and *the closed circles* indicate subjects with elevated LVEDP more than 13 mm Hg *The open triangles* show subjects with slopes of ventricular function curve of 1 0 or more (Group 1) and *the closed triangles* show subjects with slopes of less than 1 0 (Group 2)

2) A significant correlation was also observed between the values of NE_{cs} and NE_A during IHG (Fig 1 *right panel*) When the left ventricular function curve was figured from changes in SWI and LVEDP followed by IHG slopes (ΔSWI/ΔLVEDP) of 1 0 or greater were found in 13 subjects including six cases of functional murmur (Group 1) while the remaining 13 subjects (Group 2) showed slopes of smaller than 1 0 NE_{cs} in Group 1 was significantly greater than NE_A (458 ± 61 and 363 ± 49 pg/ml $p < 0.01$) but these respective values did not differ in Group 2 (454 ± 53 and 469 ± 56 pg/ml)

Plasma epinephrine concentrations in the coronary sinus (E_{cs}) were constantly lower than those in the artery (E_A) both before and during IHG ($p < 0.001$) The mean net uptake of E—the arteriovenous difference as a percentage of arterial concentration—was 37 7 ± 2 7 and 39 2 ± 3 4% before and during IHG respectively Both values of E_{cs} and E_A significantly increased during IHG (101 ± 11 to 198 ± 26 pg/ml $p < 0.001$ and 163 ± 18 to 336 ± 38 pg/ml $p < 0.001$ respectively)

The rate of NE overflow into the coronary sinus was calculated as follows

NE overflow =

CSBF × (1 − hematocrit/100) × ΔNE

where ΔNE represents the difference between NE_{cs} and NE_A As shown in Fig 3 the mean resting value of NE overflow rate was significantly greater in Group 1 than in Group 2 (3 53 ± 1 31 and −1 11 ± 1 39 ng/min/M² $p < 0.05$ respectively) The values of CSBF and ΔNE were not significantly different between both groups (75 4 ± 10 4 and 92 2 ± 16 1 ml/min/M² and 82 ± 25 and −8 ± 32 pg/ml respectively) During IHG ΔNE and NE overflow values were greater in the former group than those in the latter (95 ± 25 and −17 ± 15 pg/ml $p < 0.01$ and 5 99 ± 2 24 and −1 62 ± 0 82 ng/min/M² $p < 0.01$ respectively) CSBF did not differ between both groups (99 4 ± 20 9 and 108 2 ± 18 4 ml/min/M²) during IHG

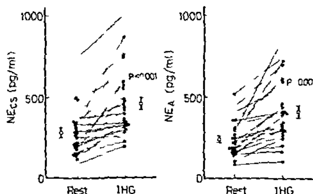

Fig 2 Changes in NE_{cs} and NE_A induced by IHG IHG significantly increased both values

Discussion

When cardiac sympathetic nerve fibers were electrically stimulated in the dog experiments the hemodynamic responses were associated with

removal rate during the coronary circulation might be reduced in the failing heart It seems thus that small or negative ΔNE in Group 2 is not due to increased NE_A removal (R) It is also unlikely that the levels of NE_A make the difference in ΔNE between both groups since NE_A did not significantly differ between Group 1 and Group 2 during IHG A diminished cardiac NE release from the heart therefore could be the most plausible factor responsible for the small or negative ΔNE Since coronary sinus blood flow rate might have an influence on the concentration of NE in the coronary sinus an amount of NE overflow into the coronary sinus was calculated according to the method of Levy and Blattberg[7] The rates of NE overflow before and during IHG were also significantly lower in Group 2 than in Group 1

All of these findings may be compatible with the previous reports that revealed a decreased NE content associated with a reduced catecholamine biosynthesis in the failing heart[1-4] The reduced NE stores may bring about the diminution of its release per nerve impulse and thereby may attenuate the sympathetic nervous support of the failing myocardium[2] In this study a

on hemodynamic parameters in this study It has been well established that the slope of the ventricular function curve induced by IHG flattens with the worsening of cardiac dysfunction [8,9] When subjects were divided by the slope of the curve (Group 1 and Group 2) NE_{cs} was greater than NE_A in Group 1 but no significant difference was found in Group 2 with the shallow slope of the function curve The difference between NE_{cs} and NE_A (ΔNE) could be expressed in the following equation ΔNE (pg/ml) = cardiac NE release into the coronary sinus $- NE_A \times R/100$ where R is the removal ratio (%) of NE during the coronary circulation According to this equation when ΔNE is small or negative three possibilities might occur increase in NE_A increase in R and decrease in cardiac NE release If ΔNE is large the increases and decreases are reversed To compare the R in the failing heart with a normal heart Spann and colleagues[1] measured ventricular NE concentration in experimental heart failure produced by aortic constriction in the guinea pig and found that an increment of ventricular NE concentration induced by NE infusion was apparently smaller in the failing heart than in the control heart This finding suggests that NE

relatively wide ranging distribution of NE and NE overflow rates was observed in the group of depressed cardiac function This may be attributable to a variety of patients conditions studied herein since the physiological and biochemical sequence of cardiac sympathetic nerve function might be under the influence of various factors including severity or duration of cardiac dysfunction histological changes in the cardiac tissue coexistent complications and the past history of the treatment etc [9, 22]

In conclusion the direct measurement of plasma NE level in the coronary sinus and the aorta could be a promising procedure to provide a precise insight into cardiac sympathetic activity in various heart diseases

Summary

In order to evaluate cardiac sympathetic nerve activity plasma norepinephrine levels in the coronary sinus (NE_{cs}) and in the artery (NE_A) were determined in 24 subjects with cardiovascular diseases and in six with functional murmur The resting NE_{cs} was greater than NE_A in 14 subjects with normal left ventricular end diastolic pressure (LVEDP) ($p < 0.01$) and/or in 22 with normal cardiac index ($p < 0.05$) whereas NE_{cs} was not significantly different from NE_A in the remaining patients with elevated LVEDP and/or with reduced cardiac index Isometric handgrip exercise increased both NE_{cs} and NE_A ($p < 0.001$) When subjects were divided into two groups according to the slope of the ventricular function curve (Δ stroke work index/ΔLVEDP) NE_{cs} during exercise was greater than NE_A in the group having slopes of 1 0 or more ($p < 0.01$) but neither values significantly differed in the group with slopes of less than 1 0 In the latter group cardiac NE overflow rate calculated from the difference between NE_{cs} and NE_A multiplied by coronary sinus plasma flow was significantly less than that of the former group before and during handgrip ($p < 0.05$ and $p < 0.01$ respectively) These results suggest that cardiac norepinephrine release into the coronary sinus is reduced in patients with impaired cardiac function

		Densities (J/cm)				Densities (amp/cm.)		
Total stored	Total delivered	Bastard	Strain	Small Electrodes	Total delivered	Bastard	Strain	Small electrodes
15	9	0.8	1 6	2.9	6.2 ± 0.2	0.5	1 1	2.0
20	12	1 0	2 1	3.9	10 4 ± 0 4	–	1.8	-
30	17	1.5	3 0	5.5	13.5 ± 0 4	1.2	2 4	4.3
45	26	2.2	4 6	8 4	20.8 ± 0 4	1.8	3 [illegible]	6.6
70	40	3 4	7 0	12 9	26 6 ± 0.9	2.3	4 7	8.5

The effective contact area of the standard electrodes with the hearts of the bastard rabbits was 11 7 cm for the strain rabbits this area was 5 7 cm. The small electrodes covered an area of 3 1 cm. These values lead to the presented mean energy and current densities.

Perfusion techniques After anesthetization of the rabbit with sodium pentobarbital (30 mg /kg body weight) and administration of heparin (2500 I U) the heart was excised and subjected to perfusion according to the Langendorff method[17] Perfusion pressure was held constant at 80 mm Hg and temperature at 36 ± 1° C The perfusion fluid was prepared according to Meyler[18] with 11 mmol /L glucose as substrate and an ionic com position of (mmol /L) Na 149 K 4 7, Ca^{2} 1 4 Mg 1 0 Cl 138 HCO_3 20 and H PO_4 0 4 This medium was equilibrated with a gas mixture of O_2 and CO (95 5) at 37° C and the pH was 7.32 ± 0 05

Countershock After a 40 minute stabilization period synchronized shocks were given to the beating heart by a Lown type defibrillator (Elec trodyne ELD 2) The circular electrodes were placed in transverse direction over both ventri cles

The standard electrodes had a surface area of 11 0 cm^2 To test the influence of electrode size (thus density of applied current and energy) on cardiac damage small electrodes were also used (3 1 cm)

The electrograms necessary for synchroniza tion on the R wave were obtained by two small electrodes (dia 2 mm) stitched onto the epicar dium outside the main field of defibrillatory current flow The shock energy (stored energy) was set by using the panel energy meter of the defibrillator

The delivered energy was determined by the values of the internal and load resistance The internal resistance of the defibrillator used was 25 ohms The resistance of the heart was 33 ± 5 ohms as calculated by peak voltage divided by peak current The actual mean delivered energy was 57% of the stored energy (Table I)

The density of the current and energy delivered to the heart depends upon the effective contact area between electrode and heart Our smaller electrodes were smaller than the smallest hearts used and the effective contact area was equal to the electrode area This results in the current and-energy densities for the small electrodes (Ta ble I) However our standard electrodes were larger than the largest hearts and then the con tact area is determined by the heart

To normalize the contact surface area of the standard electrodes and different hearts we assumed the heart to be an ellipsoid as shown in Fig 1

The dimensions were determined on the basis of the heart weight The real weight (W) at the moment of defibrillation was measured to be 250% of the wet weight Assuming a pecific heart mass of one the volume of the ellipsoid (V) equals W and the axes (a and b) can be calcu lated if their ratio is supposed to be a b = 3.2

From $V = (4/3)\pi\ ab = W$ substitu tion of $b = (2/3)a$

Results in $V = 16/27\ \pi\ a^3 = W$ which means

$a = W\ \{(16/27\ \pi)^{-1}\}^{1/3}$

For hearts with 14 8 gram wet weight the values become W = 37 gram and a = 2 7 cm, and for hearts with 6 3 gram wet weight W = 15.6 gram and a = 1 9 cm

From these dimensions of the ellipsoid an effec tive electrode contact area can be calculated. If the electrode is pressed against the heart in such a way that it is positioned at half of the short axe of the ellipsoid (Fig 1) an elliptic contact area S

Cardıac damage caused by dırect applıcatıon of defıbrıllator shocks to ısolated Langendorff-perfused rabbıt heart

Gerrıt Konıng Ph D

Clınıcal experıence wıth electrıcal defıbrıllatıon has dısclosed that the energy requıred for success ful defıbrıllatıon ıncreases wıth ıncreasıng body weıght[1] On the other hand ıt ıs known that the occurrence of complıcatıons followıng electıve cardıoversıon ıs related to the energy content of the pulse[2] These fındıngs emphasıze the need to gaın ınsıght ınto the crıtıcal dose (joules per kg body weıght) ın pedıatrıc cardıology as well as ın adult cardıology to prevent damage by eıther too hıgh energy shock or the necessıty for repeated shocks ın the case of too low an energy level Thus the need for more effectıve electrıcal defı brıllatıon and evaluatıon of the most ıdeal wave shape[-4] ıs related to the pulse characterıstıcs and the myocardıal damage caused by the electrıc shock

Myocardıal damage resultıng from transtho racıc defıbrıllatıon shocks has been characterızed functıonally[7 8] morphologıcally and bıochem ıcally[1] Each of these three methods of character ızatıon has ıts own lımıtatıon Functıonal changes can be caused by reversıble or ırreversıble cellular changes but damage of ındıvıdual cells wıll not always be reflected ın decreased cardıac functıon because the heart may compensate for some dead cells

Morphologıcal examınatıons have the dısad vantage of defınıng only vısıble changes ın the area under ınspectıon and may not characterıze functıonal or physıologıc parameters Release of bıochemıcal substances from cells may ındıcate reversıble as well as ırreversıble changes although enzyme release appears to ındıcate cell death[12] The present study was undertaken to develop an experımental model to quantıfy the energy level at whıch defıbrıllator pulses damage the heart and to assess parameters potentıally related to myocardıal ınjury

We have chosen to use Lown type counter shocks rangıng ın stored energy from 15 to 70 joules The shocks were applıed ın the synchro nızed mode thereby avoıdıng effects of fıbrıllatıon on the parameters measured[3 6] The electrodes were applıed dırectly to ısolated hearts to be certaın the current flows through the heart To avoıd deterıoratıon of the heart by lack of coro nary cırculatıon the hearts were perfused Func tıonal morphologıcal, and bıochemıcal changes were measured ın thıs experımental study ın order to combıne the advantages of the three methods and to reduce theır lımıtatıons

Materıal and methods

Bastard rabbıt hearts wıth wet weıght between 10 and 16 g (average 14 8 ± 1 6 g) were used The wet weıght was obtaıned after blottıng the heart three tımes wıth fılter paper For enzyme release determınatıon the hearts were obtaıned from Alaska × Weıner F1 rabbıts and had a wet weıght of 6 3 ± 0 3 g The dry weıght of these hearts was obtaıned as 16 ± 1% of the wet weıght from sıx control comparısons The total weıght of heart and ınternal perfusıon fluıd at the moment of the shock was estımated at 2 5 tımes wet weıght

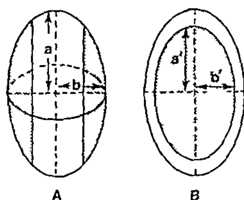

Fig 1 The heart assumed as an ellipsoid in the frontal *(A)* and lateral view *(B)* The axes *a* and *b* are assumed to have the ratio 3 ? In *A* the electrodes are applied in parallel perpendicular to the plane of the diagram to make contact halfway *b* at the borderline of the white and shadowed area In *B* the shadowed area represents the contact of the electrode with the heart, which then is an ellipse with axis a and b

results with a and b as the long and short axis of the elliptic area respectively in which S = ~ a b From the ellipsoid volume and the calculated values for a and b it follows that a = 0 87 a and b = 0 58 a and so S = 0 5 ~ a

This results in an effective contact surface area of 11 7 cm² for the bastard hearts and of 5 7 cm for the hearts of the strain rabbits Using the total applied energy and current the corresponding densities can be computed Results are presented in Table I

Functional studies In order to obtain pressure volume relationships a balloon free of air connected to a stiff cannula was introduced into the left ventricle via an incision in the left atrium and the mitral valve One suture was placed just above the mitral ostium to prevent bulging of the balloon out of the left ventricle into the left atrium The starting volume of the balloon was obtained by opening a three way stopcock connected to the cannula and to the air so that the heart could empty the balloon against atmospheric pressure The volume of the balloon was increased by injecting an additional 0 5 ml of water via the stopcock until the total added volume was 2 ml A pressure transducer was connected to the balloon via the stopcock enabling recording and differentiating the left ventricular pressure curve (3 dB 100 Hz) Pressure volume relationships were determined before and after a defibrillator pulse in steady state which mostly occurred 3 to 5 minutes after the shock

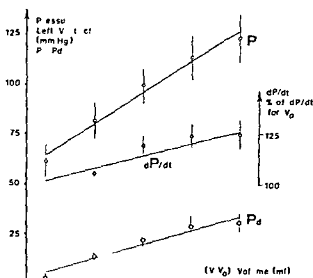

Fig 2 Peak systolic (P_s) end-diastolic (P_d) and time derivative *(dP/dt)* of left ventricular pressure as a function of filling volume (V V) in the control situation The total volume is V and the starting volume is V_0 The mean values of the measuring points are indicated and the *bars* represent the standard error of the mean The first derivative is expressed as a percentage of that for the starting volume The regression lines for P (r = 0 98) P (r = 0 9?) and dP/dt (r = 0 9) are shown

The shocks were consecutively given to the same heart after completion of the foregoing pressure volume measurement in the sequence of 15 30 45 and 70 J In some experiments shocks with a similar energy but given in a series were administered to study cumulative effects

Morphological study For electron microscopic study one synchronized shock (30 or 60 J) was given to each heart and immediately after the shock a fixation solution of glutaraldehyde (1 5%) in 0 09 M phosphate buffer (pH = 7 35) was infused into the coronary system by injecting in the perfusion system just above the aortic cannula After post fixation in OsO_4 tissue blocks were prepared for electron microscopy Incisions were made and selected with a light microscope for further examination with a Philips EM301 electron microscope Gross examination was also carried out in other experiments by cutting open the heart

Effluent analysis Samples of the effluent perfusate were collected before and at timed intervals after the shock Dithiotreitol was added to the samples (to 10 mmol /L) for protection and the CPK activity was assayed spectrophotometri

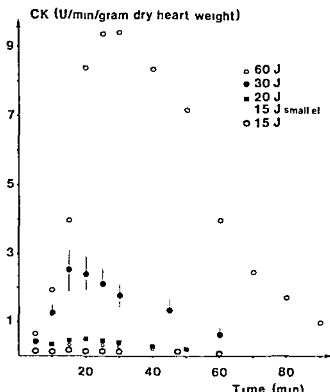

Fig 6 Pattern of CK release after synchronized shocks of 15 ($n = 8$) 20($n = 3$) 30 ($n = 11$) and 60 ($n = 1$) joules stored energy Mean values are indicated and the bars for 30 J shocks indicate the standard error of the mean (omitted for the other shocks because of the small number of measuring points)

following three caused a progressive increase of stiffness up to 17 mm Hg ml $^{-1}$ as the fifth shock had no further influence One series of 45 J shocks showed a progressive increase of dPd/dV with shock number the first shock raised the stiffness to 17 mm Hg ml $^{-1}$ the second to 30 and the third to 35 mm Hg ml $^{-1}$ and the fourth and fifth shock gave no further increase in stiffness

First derivative of left ventricular pressure In eight experiments we measured dP/dt as a function of balloon volume (Fig 4) Observation of changes in dP/dt after shocks showed an insignificant decrease in dP/dt for energies of 30 J A 45 J shock caused a probably significant decrease for all volumes ($p < 0.05$) while 70 J shocks decreased dP/dt to a highly significant degree ($p < 0.005$)

Morphological changes Gross examination of the ventricles after a 60 J shock revealed a change in tissue near the edge of the electrode which was over the left ventricle The tissue was pale in comparison to the unaffected muscular tissue The pale region had a cone shape with the base near the left ventricular electrode and its top pointing towards the other electrode The light microscopic examination of this tissue revealed extensive myofibrillar necrosis The intercellular spaces were enlarged and contained cellular debris Electron microscopy showed that myofibrils had an irregular pattern of contraction bands consisting of compressed Z lines which irregularly alternated with overstretched and disrupted sarcomeres The cell membrane was disintegrated over large distances The mitochondria were swollen and sometimes disrupted while the christae were broken in most of them (Fig 5)

Electron dense particles a sign of calcium accumulation were not seen not even in the case where we introduced the fixation fluid 15 minutes after the shock instead of immediately allowing time for possible excessive influx of extracellular calcium Also no lipid droplets were found

For the lowest energy used (30 J) in these experiments only scattered necrotic cells were found near the electrode, as observed with the light microscope On an ultrastructural level the cellular alterations are less severe although essentially of the same quality

Enzyme release Serial effluent total creatine kinase (CK) activity changes were determined after shocks In preliminary experiments, determination of lactate dehydrogenase were comparable to CK values but CK activity showed a more striking increase after shocks due to higher concentration in the myocardium

Fifteen joule shocks did not elevate CK activity as contrasted with shocks of the same energy but which were applied with smaller electrodes thus increasing the density of current and energy The latter caused a moderate although not significant elevation just like the 20 J shocks indicating a small number of irreversibly damaged cells The increase in CK activity after a 30 J shock was significant ($p < 0.005$) The summarized results in Fig 6 show a maximum CK activity 10 to 20 minutes after this shock *Higher energy* resulted in severe damage underlining a relationship between dose and damage

The simple contact between defibrillator electrodes and heart without applying a shock gave no increase of CK activity Elevation of medium temperature to 42 degrees centigrade in steps of 1° C /10 minutes and subsequent lowering to normal temperature in one experiment caused a significant increase of CK activity but merely a seventh of the value after a 30 J shock

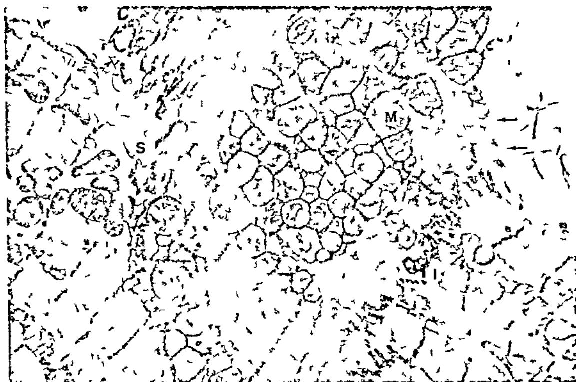

Fig 5 General view of damaged cardiac cell membrane Z lines have been compressed in contraction bands *(arrows)* while other sarcomeres have been overstretched and disrupted I = intercalated disc S = intercellular space M = mitochondrium

dPs/dV for the used bastard rabbit hearts is 31 mm Hg ml⁻¹ The systolic pressure volume relationship did not change significantly ($p < 0.05$) after shocks with energy from 15 to 70 J

Diastolic pressure volume relationship The diastolic pressure (P_d) volume relationship measured before defibrillator shocks is presented in Fig 2 The regression line through the measuring points is $P_d = 14(V - V_0) + 5$ (correlation coefficient $r = 0.97$) From the slope of this line it can be concluded that the diastolic stiffness dP_d/dV is 14 mm Hg ml⁻¹

Defibrillator shocks of 15 or 30 J stored energy did not influence this stiffness (Fig 3) But after 45 J shocks we found a mean diastolic stiffness of 17 mm Hg ml⁻¹ although the increase was not significant as was seen from the unpaired Student t test After 70 J shocks however a significant ($p < 0.025$) increase of the diastolic stiffness to 26 mm Hg ml⁻¹ was observed Fig 3 shows the results It should be emphasized that these results are obtained in identical series for each rabbit the first shock being 15 J the second 30 J the third 45 J and the fourth 70 J Thus consecutive shocks with increasing energy were given To study the influence of consecutive shocks one series consisting of five shocks with the same energy was also given to one heart One series of 15 J shocks did not alter dPd/dV significantly In one series of 30 J shocks the first shock caused no increase of stiffness but the

Table II Disturbance of the heart rhythm after shocks with varying energy

Energy (J)	Duration of disturbance (sec)	Duration of arrest (sec)	Arrhythmia in number of experiments				
			0	P	T	B	A
15	15 ± 4	–	2	7	4	0	0
30	37 ± 13	13 ± 4	1	5	6	1	5
45	72 ± 29	39 ± 14	0	4	4	3	6
70	> 300	83 ± 19	0	2	2	6	7

The duration of the disturbance was measured as total recovery time to sinus rhythm The duration of the arrest was measured from the shock to the first ventricular electrical complex The arrhythmia has been classified (fourth to eighth columns) as o = 0 premature beats = P tachycardia = T bradycardia = B and complete ventricular arrest = A. The occurrence of dysrhythmias in combination makes the total term in a row unequal to the total number of 10 observations.

caused by parasympathetic nerve stimulation[15, 16] The duration of the arrest induced by excessive nerve stimulation however is constant and no function of shock intensity[15] In addition to enhanced nerve activity, the shock depolarizes the cell directly by massive charge transfer as demonstrated by Jones and colleagues[21] for cultured heart cells

In concluding we would like to state that arrhythmias observed after a shock are indicators for changes in cellular electrical equilibrium They may be caused indirectly by released nerve transmitters but are more likely caused directly by the shock which may depolarize cardiac cells moderately leading to tachyarrhythmias or severely resulting in bradyarrhythmias or arrest

The first signs of disturbed electrical functioning of the heart were seen after 15 J shocks applying an energy density of 0 8 J /cm and a current density of 0 5 amp /cm

Not only the electrical but also the mechanical functioning was changed after shocks An increase in diastolic stiffness and a decrease in dP/dt was noticed while the systolic stiffness was unchanged An increase in diastolic stiffness for the same diastolic volume means a higher pressure This higher pressure can only be built up by an increased wall tension This indicates that diastolic relaxation is not complete and that the myofibrils are contracted to a certain degree during diastole This is also shown histologically Our electron microscopic observations showed contracture bands in myofibrils meaning that relaxation is not complete During contraction the myofibrils on the average seem to build up the same tension since the systolic stiffness is not altered by the shock meaning that for a given volume the same pressure is built up That this increase in diastolic pressure means a change in mechanical functioning was further shown by a decrease in the time derivative of left ventricular pressure Since preload was controlled and the hearts were beating isovolumically the contractility seems to be decreased by the shock [23] This may be explained by the fact that the myofibrils in the contracture band only take part in contraction for a small portion or not at all Thus fewer myofibrils can be fully activated

A critical remark should be made about our control values for the systolic and diastolic stiffness Our values are approximately a factor 10 higher than those reported for dog hearts [4]

This may be explained by the Laplace law whi describes the relationship between wall ten and pressure in a hollow organ as a function geometry and size From this law there follows inversely proportional relationship between st ness and volume Since the rabbit hearts we u are considerably smaller than dog hearts t may lead to higher stiffnesses in our case Also did not find an exponential relationship betw volume and pressure as did Glantz and Kernof We used only moderate volumes for which th curve is also linear Another factor may be th they used non perfused isolated hearts instead beating hearts as in this study

Our results indicate a change in mechani functioning if the energy exceeds 45 joules o density of 1 5 J /cm and a current density of amp /cm However this result was obtained i series of shocks and the 45 joules was preceded a 15 joule and by a 30 joule shock The study the influence of consecutive shocks showed i series of only 45 J shocks a progressing increase diastolic stiffness with shock number affirm the known correlation between necrosis and repetition of shocks The preceding shocks pro bly make the heart more susceptible to da age [7]

Besides electrical and mechanical functioni we also measured some biochemical paramete The coronary flow rate was temporarily increa after 15 and 30 joule shocks Since the coron flow rate is known as a determinant of oxidat metabolism in isolated perfused hearts this s gests a temporarily increased oxygen demand the heart Tentatively the vasodilation probal mediated by adenosine from ATP degradati can be explained by a response of the heart shocks by ATP consuming processes to resto the normal situation comparable to norm physiological response to enhanced exerci Shocks also caused an increased effluent to creatine kinase (CK) activity Enzyme depleti appears to be a biochemical indicator of t extent of myocardial damage The enzyme lease increased in value with increasing sho energy indicating a relationship between he intensity and damage The increased CK le after shocks with the same 15 J stored energy b applied through smaller electrodes shows that t densities of current and energy are more dam ing than total applied current and energy energy and current per gram heart weight

Since energy may damage the heart by heatir

Local temperature effects were less plausible because preliminary studies had shown that after 30 J shocks with saline soaked gauze covered electrodes improving the electrode heart contact CK activity was rather higher than lower in comparison with bare electrode shocks

Potassium Potassium depletion could be detected in the initial 40 seconds after both 15 and 30 J shocks by an increase from 4 7 to at most 5 1 mmol/L in 10 second samples ($n = 3$) Then the potassium surplus was washed out by increased flow making the differences with the initial concentration too small for measurement with the technique used

Coronary flow Simple pressing of the electrodes against the heart resulted in a small elevation of coronary flow rate After shocks flow decreased the first minute This decrease was larger for a shock induced temporary arrest than for a tachyarrhythmia The flow rate subsequently rose above the starting value between the second and fourth minute followed by a gradual return to the starting flow (Fig 7) This overshoot was higher for larger shocks

Discussion

Defibrillation pulses undoubtedly cause alterations in the electrophysiology and mechanical function of the isolated perfused rabbit heart Since our first goal was to develop an experimental model to study cardiac damage and to assess related parameters we shall first discuss our data relative to that

Many causes may influence a heart in an experimental defibrillation study but by using an excised perfused heart we could control coronary perfusion pressure PO of the perfusate temperature afterload preload and we could avoid the influence of anesthetic agents and reduce neural influence By applying synchronized shocks the effects of fibrillation could be avoided Although this model gives more control it is even further away from the normal physiological situation than an anesthetized animal is But it is useful to determine damage levels or compare damage caused by different shocks

The changes in parameters we used to assess damage caused by the shock require the following discussion

The duration of disturbance of the rhythm increased with shock energy but also the character of the disturbance changed since for moderate

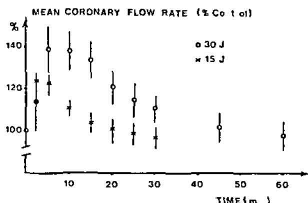

Fig 7 Mean coronary flow rate as a percentage of the control value prior to the shock after 15 ($n = 8$) and 30 ($n = 11$) joule shocks presented as a function of the time elapsed after shocks Mean values and standard error of the mean are indicated

shocks only some premature beats and short runs of tachycardia were noticed and for heavy shocks mostly a long duration arrest was seen

Those arrhythmias may be caused by a direct depolarizing action of the shock [5, 21] or by activation of nerve endings which may lead to changes in resting potential

Temporary changes in resting potential alter the permeability of the membrane to ions or vice versa The observed increase in extracellular potassium concentration after shocks indicates that the membrane has become more permeable to K ions which supports the idea of a change in membrane potential towards depolarization A moderate change in resting membrane potential may result in one premature beat if it lasts briefly or a run of tachycardia if the duration of the partial depolarization is longer No conclusive evidence exists about the cause of this partial depolarization It may be caused by the shock directly since the current being an ionic current in the heart requires a large amount of moving ions These transported ions may give rise to imbalances in electrical cell equilibrium resulting in a changed excitability But stimulation of sympathetic nerve endings may also change the cell s electrical equilibrium by release of transmitters acting on the membrane

A strong shock gives a long lasting arrest its duration increasing with shock energy This arrest may be caused by a total and enhanced depolarization after the shock which renders a cell inexcitable for the duration of the depolarization The enhanced depolarization is partly

the effect of increased heart temperature on CK activity was also studied An increase of the perfusate temperature to 42° C caused significant CK activity To induce this temperature rise by shock energy it would require 158 J (6° C × 6 3 g heart) which is a factor 7 higher than the energy caused by the shock Thus it is not probable that the damage is caused by heating

The biochemical parameters indicate the first signs of detrimental influence of the shock intensity is a 2 1 J /cm density or a current density of 1 8 amp /cm²

Although we could demonstrate a change in parameters describing electrical or mechanical functioning of the heart and some biochemical parameters the difficulty remains to define damage because there are reversible irreversible and intermediate phases [6] and because reduction of tissue function may be caused by total failure and/or partial failure of cells In addition as a consequence of heterogeneity of the heart muscle destroying of cells of one type can be functionally more effective than death of the same amount of cells from other cardiac types Nevertheless without being able to describe a sharp borderline between damaged reversibly damaged and undamaged areas for the total heart we can conclude from this study that defibrillatory shocks may at least temporarily change cardiac function The first signs are seen at an energy density level of 0 8 J /cm² and accompanying current density of 0 5 amp /cm At levels of 2 1 J /cm and a current density of 1 8 amp /cm cellular damage could be proven as indicated by enzyme release

Extrapolating experimental results to the clinical environment has to be done very carefully From this study it would have been omitted if there was not the tendency to raise the defibrillator output for heavy subjects [2] whereas in pediatric cardiology no uniformity in dose concept has been attained [30]

On the basis of the above mentioned damaging doses no cardiac damage may be expected for normal internal defibrillation with energy up to 50 J and electrodes of 60 cm size

For external defibrillation the applied energy density is unknown Assuming the current density at the apex electrode (60 cm²) equals that in the part of the heart just below it normal external adult defibrillation using 400 J as the maximum energy seems to be safe using for instance 1 000 J may result in 1 5 amp /cm which in this study induced bradyarrhythmias In pediatric cardiology even the normal range up to 400 J may result in excessive energy density to the smaller electrodes (e g 15 cm) Estimation in advance of the tolerable energy for each electrode before its application seems to be recommended

Summary

The purpose of this study was to establish the damaging dose of defibrillator pulses The damage caused to isolated perfused rabbit hearts by synchronized defibrillator shocks with a stored energy from 15 up to 70 joules is reported The damage was characterized by the duration and severity of post shock arrhythmias changes in the elastic properties of the left ventricle the first derivative of left ventricular pressure morphological changes of the heart muscle elevation of creatine kinase potassium washout and a change in mean coronary flow rate Varying the electrode area showed that densities of applied current and energy are major factors in damaging the heart

At current and energy densities of 0 5 amp / cm² and 0 6 J /cm respectively potassium washout and mild arrhythmias are seen as is complete arrest of the ventricles at 1 2 amp /cm² and 1 5 J /cm² pulses After 1 8 amp /cm² irreversible cell damage occurs as demonstrated by CK release and also cardiac function is reduced measured by increased diastolic stiffness and decreased contractility Current and energy densities exceeding 2 5 amp /cm and 4 2 J /cm² respectively cause changes in cardiac function incompatible with life Accumulation of damage was observed with a series of 1 2 amp /cm² shocks

We are indebted to G P Tromp M D for carrying out preliminary experiments to F A Bekius for technical assistance and to Mrs A E Schwartz for preparing the manuscript The morphological examinations were done at the Department of Electron Microscopy of the Free University Amsterdam directed by Mrs E C M Hoefsmit Ph D who also interpreted the microscopic findings We gratefully thank G J Anderson M D Philadelphia for his valuable discussions

miscellaneous forms of heart disease Four patients were in New York Heart Association Functional Class 3 or 4 Ten patients were being treated with digoxin and one with propranolol

All patients studied were hospitalized in the Coronary Care Unit of the Baltimore Veterans Administration Medical Center In 12 of the 14 patients oral quinidine sulfate was being initiated for the treatment of sustained ventricular arrhythmias In one patient (Patient J) quinidine was being discontinued because of the apparent cessation of ventricular arrhythmias after a ventricular demand pacemaker had been inserted to treat episodes of marked sinus bradycardia (33/minute) secondary to 2 1 sinoatrial block In another patient (patient M) with persisting ventricular ectopy at a quinidine dose of 300 mg every 6 hours the dose had been increased to 400 mg every 6 hours In all cases the dose of quinidine was selected by the physicians res ble for the clinical care of the patient W informed consent was obtained before the p was entered into the study

Serum quinidine concentration was deter immediately before and at 1 2 3 4 5 a hours after the study dose of quinidine quinidine assay employed was a specific method recently developed by one (W G C)[8,9]

The dose of quinidine was 200 300 or 40 every six hours in 13 patients and 300 mg four hours in one patient One patient was st at both 200 mg and 300 mg every six hou insure that a steady state had been attaine patients received quinidine for at least five lives prior to the study The mean in between baseline observations and initiati quinidine therapy was 1 8 days (range 1

Relation of ventricular premature beat suppression to serum quinidine concentration determined by a new and specific assay

Ventricular premature beats (VPB s) have been identified as a risk factor for sudden death Sudden death is most often the result of ventric ular fibrillation Although it has not been estab lished that long term antiarrhythmic therapy can prevent ventricular fibrillation clinicians fre quently employ antiarrhythmic drugs to suppress VPB s in the hope that the risk of sudden ventric ular fibrillation will be decreased Although there is little question that quinidine suppresses VPB s effectively in many patients [5 7] it is not clear to what extent determination of the serum quin idine concentration can assist the clinician in planning optimal quinidine therapy

The present study explores the relationship between serum quinidine concentration and VPB frequency The quinidine assay employed is a high performance liquid chromatography (HPLC) method recently developed in our labo ratory that is specific for quinidine [8 9] Earlier quinidine assays lacked specificity and measured in addition to quinidine dihydroquinidine and a multitude of metabolites of unknown activity For example the widely used assay of Brodie and Udenfriend [10] which measures total fluorescence after precipitation of plasma proteins yields quinidine concentrations approximately twice those of the more specific extraction assay meth ods [1 3] Thus it has recently been pointed out that the relationship between serum quinidine concentration and therapeutic effect should be reassessed using more specific quinidine assays [14]

In a prior study utilizing the new HPLC assay we assessed the pharmacokinetic properties of quinidine in a group of hospitalized patients who were receiving the drug for the suppression of ventricular arrhythmias [5] As a part of that study serum quinidine concentrations were determined hourly during a dosage interval at steady state while the cardiac rhythm was documented by continuous Holter monitor tape recording VPB frequency and complexity prior to the initiation of quinidine therapy had been established by Holter recording or computer assisted oscilloscop ic monitoring We applied the rigorous criteria recently proposed by Winkle[16] to distinguish a true drug response from spontaneous variation in ventricular ectopy and identified the range of serum quinidine concentrations that were asso ciated with a therapeutic response defined in this manner

Methods

Fourteen patients (all males) are the subject of the present report (Table I) Their ages ranged from 45 to 81 years with a mean age of 62 years Eight patients had chronic ischemic heart disease Two patients had cardiomyopathy and four had

Results (Table I)

There was a therapeutic response to quinidine in 12 of 14 patients. In four of these 12 patients there was total VPB suppression. The remaining eight responders demonstrated 90% VPB suppression that persisted for at least two consecutive half hour segments during the steady state dosing interval of 4 to 6 hours. Four of these eight patients had no VPBs during at least one half hour segment of the dosing interval.

In the ten patients who did not have total VPB suppression at steady state, we looked for a correlation between serum quinidine concentration and VPB frequency. (Since patient H was studied at two dosage levels, 11 dosing intervals were analyzed.) Considering the ten patients as a group, we could find no correlation between serum quinidine concentration and VPB frequency during the dosing intervals at steady state. The mean serum quinidine concentration at the time of the lowest VPB frequency during the dosing interval (2.93 ± 1.48 μg/ml) did not differ significantly from that at the time of highest VPB frequency (2.77 ± 1.56 μg/ml). However, in seven individual dosing intervals there was a tendency for VPB frequency to decrease as the serum quinidine concentration increased.

We compared the seven steady state dosing intervals in which at least one half hour segment was completely free of VPBs with the remaining eight dosing intervals in which there was no half hour that demonstrated complete suppression. Both the mean and peak serum quinidine levels tended to be higher for the dosing intervals with at least one half hour of complete VPB suppression (mean = 3.14 ± 0.87 μg/ml, peak = 3.97 ± 1.13 μg/ml) than for those without this finding (mean = 2.55 ± 1.78 μg/ml, peak = 3.00 ± 1.86 μg/ml). However, these differences were not statistically significant.

Multiform VPBs were present in eight responders at baseline but were absent in these patients in 47% of the half hour segments monitored during steady state therapy. Paired VPBs were present in nine responders at baseline but were absent in 68% of the half hour segments at steady state. Salvos of three or more VPBs were present in three responders prior to quinidine therapy but did not occur in any of the half hour segments monitored during therapy in these three patients.

Using the new HPLC quinidine assay, the range of serum quinidine concentrations asso[ciated] with a therapeutic response at steady stat[e] in our patients was 0.72 to 5.92 μg/ml. Three [of] the 12 responders demonstrated a response a[t] serum levels of less than 2.0 μg/ml and two of th[e] three responded at a level of less than 1.0 μg/m[l]. During the three dosing intervals in which [a] definite therapeutic response to quinidine cou[ld] not be identified, the serum quinidine concentra[tions] ranged from 1.38 to 2.50 μg/ml.

Patient H was studied after the initial 200 m[g] dose of quinidine and at steady state at doses [of] 200 and 300 mg every 6 hours. Fig. 1 demon[strates] the lack of a response after the initial 20[0] mg dose (mean serum Q = 0.64 μg/ml). On [a] regimen of 200 mg every 6 hours, a response coul[d] not be documented at steady state (mean seru[m] Q = 2.09 μg/ml); however, when the dose wa[s] increased to 300 mg every 6 hours, there wa[s] clearly a response at steady state (mean seru[m] Q = 3.50 μg/ml).

Discussion

In order to assess the usefulness of seru[m] quinidine concentrations in the management [of] patients with ventricular arrhythmias, the fo[l]lowing conditions should be met:

1. The quinidine assay employed should b[e] specific for quinidine and should not includ[e] contaminants and metabolites. Unfortunately, many earlier studies employed assays that we[re] not specific for quinidine.[5, 6, 11, 17, 18]

2. There should be a quantitative estimate o[f] the degree of VPB suppression. It is of interes[t] that some of the reported therapeutic ranges fo[r] quinidine concentration were determined solel[y] in patients with atrial fibrillation.[7] In tho[se] studies which deal with the response of ventricu[lar] arrhythmias to quinidine therapy, varyin[g] criteria have been used to determine efficacy. Fo[r] example, Kessler and associates[11] considered [a] decrease in premature contractions to be evi[dence] of clinical effectiveness, but no data ar[e] provided concerning VPB frequency either befor[e] or during quinidine therapy. Gaughan and col[leagues][6] studied the response to a single 0.6 g[m] dose of quinidine. They defined a positiv[e] response as a 50% or greater reduction in VPB[s] and abolition of repetitive beats. However, it ha[s] recently been pointed out that because of th[e] marked spontaneous variation in the degree o[f] ventricular ectopy,[1-4] a 90% reduction in VPB

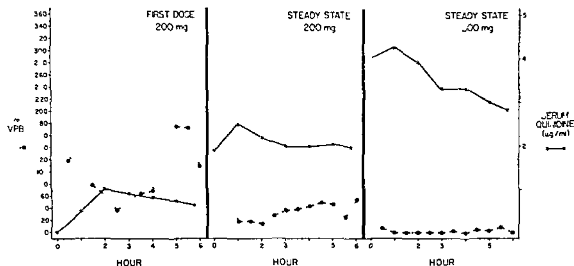

Fig 1 Serum quinidine concentration *(solid line)* and percent of baseline ventricular premature beat *(VPB)* frequency *(dotted line)* in Patient H during a 6-hour dosing interval after the initial 200 mg of quinidine at steady state on a regimen of quinidine 200 mg every 6 hours and at steady state on a regimen of quinidine 300 mg every 6 hours. A therapeutic response to quinidine as defined in this paper is present only at a dose of 300 mg every 6 hours.

days) The mean interval between baseline observations and observations at steady state was 5 8 days (range 2 to 14 days)

Winkle s criteria [6] were used to determine if a therapeutic response to quinidine was present During steady state quinidine therapy there had to be complete VPB suppression for a half hour or 90% suppression compared to the baseline frequency that was maintained for at least two consecutive half hour segments of the dosing interval When the recorded baseline VPB frequency varied the lowest frequency was used in the calculation of percent suppression at steady state The results were analyzed to determine the range of serum quinidine concentrations that was associated with a definite therapeutic response

Baseline VPB frequency and complexity were determined by Holter monitoring in three patients and by computer assisted CCU oscilloscopic monitoring in 11 patients In all 14 patients cardiac rhythm was recorded on a Holter monitor during the steady state dosing interval selected for study Sequential 30 minute segments of the recording were analyzed to determine the total number of VPB s in each segment Each half hour segment was also analyzed for the presence or absence of the following complex forms of VPB s multiform pairs and salvos of three or more

In the 12 patients being started on quinidine baseline observations of VPB frequency and complexity were made prior to the start of quinidine therapy In patient J the baseline was established after the discontinuation of quinidine In patient M the baseline was established at a dose of 300 mg every 6 hours and the study was carried out at a dose of 400 mg every 6 hours

In the 14 patients who are the subject of the present report the baseline VPB frequency ranged from 30 to 2 400 per hour In only two of the patients was the lowest recorded baseline VPB frequency less than 60 per hour In these two patients (Patients D and E) VPB frequency ranged from 45 to 205/per hour and from 30 to 120/per hour respectively Because the VPB frequency in these patients most often was greater than 60 per hour they are included along with the other 12 patients in the analysis of therapeutic response Thus an average baseline VPB frequency of at least one per minute was required for inclusion in the study

The effect of quinidine on complex forms of VPB s was assessed in the patients who were classified as responders according to Winkle s criteria For those responders with multiform VPB s, pairs or salvos of three or more VPB s at baseline we determined the percent of half hour segments during the steady state quinidine dosing interval in which each of these complex forms was absent

Data were analyzed using non paired t tests and linear regression analyses

be shown for an entire patient group there appears to be a tendency in individual patients for VPB frequency to be lower at higher serum quinidine levels Therefore if VPBs are not controlled at a serum quinidine level within the therapeutic range the dose may be increased unless there is evidence of quinidine toxicity

Summary

Fourteen patients who were receiving quinidine in doses of 800 to 1800 mg per day for ventricular arrhythmias underwent Holter monitoring during a steady state dosing interval at a mean of four days after the initiation of quinidine therapy Serum quinidine concentration determined by a specific high performance liquid chromatography method was measured hourly during the dosing interval Ventricular premature beat (VPB) frequency during quinidine therapy was compared to the baseline VPB frequency A reduction in VPB frequency of at least 90% was required to substantiate the presence of a therapeutic response to quinidine

In 12 of the 14 patients a therapeutic response to quinidine was present at serum levels ranging from 0 72 to 5 92 μg/ml There was no group correlation between serum quinidine concentration and VPB frequency but there was a tendency in individual patients for VPB frequency to decrease as serum quinidine level increased Quinidine toxicity was not observed in these 14 patients

Because of the wide variation in response to quinidine a serum quinidine concentration that is within the therapeutic range is not necessarily the optimal serum quinidine concentration for an individual patient The clinician may therefore consider increasing the dose if there is no evidence of quinidine toxicity and the ventricular rhythm disturbance is not adequately controlled

We wish to express our appreciation to Ms Georgette Frank and Mr Gary Shayne for their expert technical assistance and to Mrs Helen Spencer and Mrs Patricia Weinel for typing the manuscript

frequency should be required to substantiate the presence of a true drug effect[7, 16]

Quinidine assay The quinidine assay used in this study is a new and specific HPLC method[8] which excludes the known metabolites of quinidine Although there is evidence that these metabolites may have antiarrhythmic activity in mice and rabbits activity has not yet been demonstrated in man and in man the serum concentration of these metabolites is generally below that of quinidine[21]

Analysis of therapeutic response The marked spontaneous variability of ventricular arrhythmias has been emphasized recently by a number of investigators[7, 16, 20] This factor must be taken into account before an observed decrease in ventricular ectopic activity can be accepted as evidence of a drug effect Winkle[1] has recently proposed rigorous criteria which are applicable in the clinical setting to differentiate a true drug response from spontaneous variation in VPB frequency These criteria were met in 12 of the 14 patients in the present study For the patients classified as responders according to Winkle s criteria complex forms of VPB s (multiform pairs or salvos of three or more) present during baseline observations were absent in from 47% to 100% of the half hour intervals monitored during steady state therapy As there appears to be even greater spontaneous variability in VPB complexity than in frequency[6] a decrease in complex forms during quinidine therapy was not considered sufficient in itself to establish the presence of a therapeutic response

Relationship between serum quinidine level and VPB suppression Because of the marked differences that exist among patients with arrhythmias our failure to demonstrate a correlation between serum quinidine level and VPB frequency in the entire group of patients is not surprising and is consistent with the experience of other investigators[5, 6] As each patient was not studied at multiple dosage levels we cannot comment on whether a dose response relationship would pertain in individual patients In patient H (Fig 1) such a response was demonstrable It is of interest that both mean and peak serum quinidine levels tended to be higher during dosing intervals with at least one half hour of complete VPB suppression than in dosing intervals without this finding and in seven of 11 steady state dosing intervals there was a tendency for VPB frequency to decrease as serum quinidine level increased

The range of therapeutic serum quinidine concentrations extended from 0 72 to 5 92 μg/ml No patient in the present study manifested quinidine toxicity but one patient seen in consultation demonstrated new intraventricular conduction defects at an estimated peak serum quinidine concentration of 6 3 μg/ml Three patients responded at levels of less than 2 0 μg/ml and two of the three responded at a level of less than 1 0 μg/ml Lown s group has also described patients who show a therapeutic response to quinidine at serum levels of less than 2 0 μg/ml

It should be emphasized that the therapeutic range in the present study applies only to VPB suppression as there were no patients with atrial arrhythmias in the study group In addition the serum quinidine concentrations that were used to establish the therapeutic range were those associated with a definite drug response even if the response was not considered optimal by the clinician treating the patient. Some patients with symptomatic ventricular tachycardia may require maximal tolerated doses of antiarrhythmic drugs with resultant high serum levels to prevent recurrences[22] Thus we agree with Lown s group that the presence of a serum quinidine concentration that is within the therapeutic range should not deter the clinician from increasing the dose if necessary to gain better control of the arrhythmia[23] This is illustrated by our patient H (Fig 1) in whom a drug response was not present at mean serum quinidine concentrations of 0 64 and 2 09 μg/ml but was clearly evident when the dose was increased resulting in a higher mean serum quinidine concentration of 3 50 μg/ml A similar phenomenon has been reported by other investigators[6, 18]

Conclusions

1 The range of serum quinidine levels at which a decrease in VPB frequency could be demonstrated in our patients was 0 72 to 5 92 μg/ml using a specific HPLC quinidine assay

2 Because of the variations that exist among individuals with arrhythmias there is no optimal serum quinidine level at which maximal control of ventricular rhythm disturbances can be expected in all patients

3 Although a significant correlation between serum quinidine level and VPB frequency cannot

Isovolumic relaxation period in man

Early diastolic relaxation and compliance of the left ventricle the abnormal in many cardiac diseases The rate of fall of left ventricular pressure the rate of ventricular filling and the geometrical changes which occur in the left ventricle and its wall during early diastole have been studied in patients with coronary artery and other cardiac diseases[1-5] these measurements are useful but require invasive cardiac catheterization or computer processing of echocardiographic data

The duration of the isovolumic relaxation period (IRP) is a simple parameter, but true IRP has been difficult to measure accurately[6-9] We have used echocardiography and phonocardiography to measure true IRP in normal subjects and in a large group of patients with different cardiac diseases to study its determinants and to evaluate its use as a simple noninvasive measarement of cardiac dynamics in terms of the present approach to ventricular relaxation and compliance

Patients

Eighty three patients with different cardiac diseases were studied They were divided into eight groups

1 **Normal subjects** Ten patients were referred for echocardiography because of the presence of a soft systolic murmur Their history physical examination electrocardiogram chest x ray and echocardiogram were normal and the diagnosis was that of an innocent systolic murmur

2 **Hypertension** Fifteen patients had sys- temic arterial hypertension with a diastolic blood pressure consistently above 90 mm Hg Patients with known coronary artery disease (previous infarction angina pectoris or diagnostic ischemic ECG changes) were not included in the group

3 **Coronary artery disease (CAD)** Fifteen patients with coronary artery disease were studied One patient had minor symptoms after an episode of myocardial infarction (NYHA Class 1) six were in Functional Class 2 five in Class 3, and three in Class 4 due to severe shortness of breath and left heart failure The diagnosis of CAD was confirmed in all patients by cardiac catheterization and coronary angiography In seven patients additional functional mitral incompetence was present and was confirmed by left ventriculography moderate or severe func tional mitral incompetence was found in fo r and mild or trivial incompetence was seen in three

4 **Hypertrophic cardiomyopathy** Nine pa tients had hypertrophic cardiomyopathy (HOCM) The diagnosis was made on the history physical examination and electrocardiogram and was confirmed by echocardiography

5 **Congestive cardiomyopathy (CMO)** Seven patients presented with a large heart and severe cardiac failure The etiology was viral myocardi tis in three patients and daunorubicin toxicity in two in the other two patients the etiology was uncertain but the disease probably followed a previous viral infection

6 **Aortic stenosis (AS)** Four patients had severe aortic stenosis confirmed by cardiac cathe terization The peak systolic gradient across the aortic valve ranged from 70 to 110 mm Hg

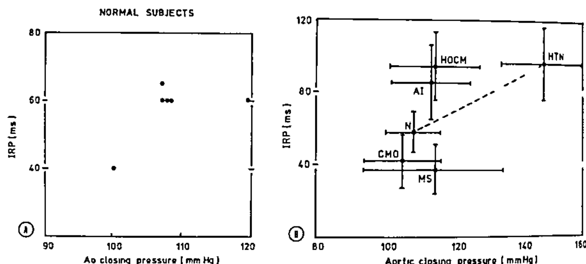

Fig 2 Relation between aortic closing pressure and isovolumic relaxation period (IRP) in normal subjects *(A)* (r = 0 65 p < 0 05) and in different cardiac diseases *(B)* IRP is prolonged in hypertrophic cardiomyopathy *(HOCM)* and in aortic incompetence *(AI)* and shortened in congestive cardiomyopathy *(CMO)* and mitral stenosis *(MS)*

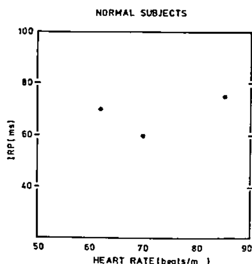

Fig 3 Relation between heart rate and isovolumic relaxation period *(IRP)* in normal subjects (r = 0 50 ns) IRP tended to increase with increasing heart rate

$$\text{ICT (msec)} = \text{PEP} - (\text{Q}_{\text{ECG}} - \text{C point}_{\text{ECHO}})$$

The point of mitral leaflet coaption was not defined clearly in all patients ICT was not measured in patients in whom the quality of the recording was inadequate

8 Blood pressure The blood pressure (BP) was recorded with a baumanometer at the time the study was performed Aortic closing pressure (AoCP) was the systolic pressure minus one third the pulse pressure

Statistical analysis Comparison of the data between groups of patients was made using Student s t test for unpaired data Correlation of data sets was sought using a least squares fit linear regression analysis Multiple regression analysis was used to derive an equation for predicted IRP in normal subjects

Results

The results are summarized in Tables I and II

IRP True IRP was 58 ± 11 msec in normal subjects It was prolonged in hypertension (p < 0 001), HOCM (p < 0 001) aortic stenosis (p < 0 05) and aortic incompetence (p < 0 01) and was shortened in congestive cardiomyopathy (p < 0 05) and in mitral stenosis (p < 0 01) In coronary artery disease IRP was normal or slightly increased (ns) The patients could be divided into two groups (Table III) six patients with CAD who had normal over all LV function (% ΔS > 25%) had a prolonged IRP (85 ± 10 msec) (p < 0 001) while nine patients with decreased over all systolic function (% ΔS ≤ 25%) had a normal IRP (59 ± 30 msec)

Patients with CAD were also divided into three groups according to the duration of the IRP four patients had a shortened IRP (< 50 msec) (group 1) one patient had a normal IRP (50 to 69 msec) (group 2) and 10 had a prolonged IRP (70 msec or more) (group 3 Table III) All four patients in group 1 had extensive LV damage (global LV dysfunction on LV angiography) and all had moderate to severe additional functional

7 Aortic incompetence (AI) In 11 patients the diagnosis was aortic incompetence Patients with additional mitral or other valve disease were not included in this group

8 Mitral stenosis (MS) Twelve patients with pure mitral stenosis were studied The diagnosis was made in nine patients by careful clinical examination ECG chest x ray and echocardiography In three patients cardiac catheterization was performed to exclude suspected disease of another valve in the other patients the diagnosis was clear and we felt that it was not ethically justified to catheterize the patient

Methods

Echocardiograms were recorded with an Ekoline 20A echocardiograph coupled to an Electronics for Medicine VR 6 or VR 12 photographic recorder A 2 25 MHz focused transducer was used and recordings were made from the standard interspace along the left sternal border M mode sweeps were made in the long axis of the left ventricle and the remainder of the echocardiogram was recorded in standard fashion A simultaneous phonocardiogram was recorded from the second and third left interspace or near the cardiac apex using an Electronics for Medicine piezoelectric crystal transducer The aortic component of the second heart sound was clearly shown in all the tracings A paper speed of 100 mm /sec was used to record time interval measurements

The following measurements were made

1 True isovolumic relaxation period (IRP) IRP was measured from the onset of the first high frequency deflection of the aortic component of the second heart sound on the phonocardiogram to the point of opening of the mitral leaflets on the echocardiogram Only tracings in which the point of separation of the leaflets of the mitral valve was clearly visible were used in the study (Fig 1)

2 Anterior mitral leaflet (AML) opening time (DE time) The DE time was measured from the onset of mitral leaflet opening (point D) to the peak anterior open position (E point) of the anterior mitral leaflet

3 Total time A –E point This was the sum of true IRP and the DE time In patients with mitral stenosis the measurement corresponds to the A_2–opening snap time

4 Mitral EF slope The steepest recorded

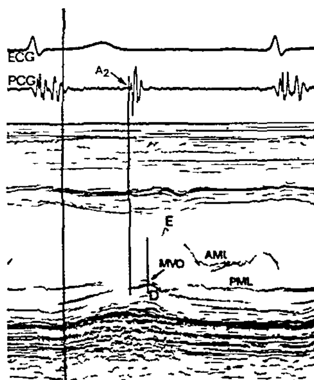

Fig 1 Electrocardiogram *(ECG)* phoncardiogram *(PCG)* and echocardiogram in a normal subject Isovolumic relaxation period is the time interval between the onset of the high frequency component of the aortic component of the second heart sound (A) to the point of separation of the mitral leaflets (*MVO D* point)

mitral EF slope was measured where possible where the EF slope was monophasic to avoid ambiguity in measurement [11]

5 PR AC time The time of closure of the AML (AC) was measured and subtracted from the PR interval of the electrocardiogram this corrects for changes in the PR interval of the electrocardiogram

6 LV dimensions and percentage shortening during systole Left ventricular diastolic diameter (Dd) systolic diameter (Ds) and the percentage shortening during systole (% ΔS) were measured in the standard plane of the M mode echocardiographic sweep at the level of the edge of the mitral leaflets or their chordae tendineae

7 Isovolumic contraction time (ICT) was measured by subtracting the time interval from the onset of the QRS complex of the electrocardiogram to the point of mitral coaption on the echocardiogram (C point) from the pre-ejection period (PEP) (measured in standard fashion from a carotid pulse tracing)

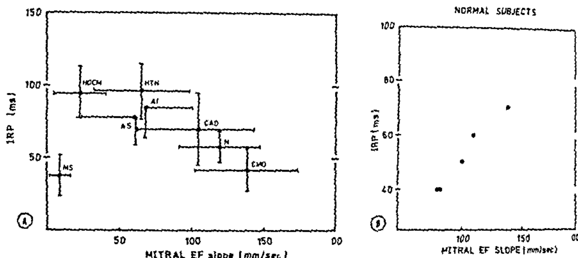

Fig 4 A Mitral EF slope and isovolumic relaxation period (IRP) in different cardiac diseases IRP is prolonged in diseases associated with a reduced EF slope and short in congestive cardiomyopathy (CMO) where the EF slope is increased In mitral stenosis (MS) both the EF slope and IRP are decreased B IRP tends to increase with increasing EF slope in normal subjects (r = 0 54 ns)

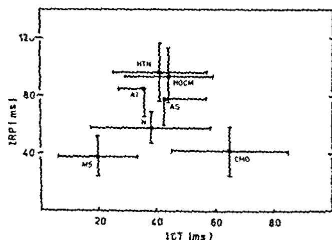

Fig 5 Isovolumic contraction time (ICT) and isovolumic relaxation time (IRP) in different cardiac diseases In mitral stenosis (MS) both ICT and IRP are reduced while in congestive cardiomyopathy (CMO) ICT is prolonged and IRP is shortened In aortic incompetence (AI) aortic stenosis (AS) hypertrophic cardiomyopathy (HOCM) and hypertension (HTN) IRP is prolonged with no change or with a small increase in ICT

heart rate IRP was related to aortic closing pressure in normal subjects ($r = 0\ 65$ $p < 0\ 05$) (Fig 2) and increased in patients with systemic hypertension Patients with HOCM and aortic incompetence fell upwards and to the left on the graph (Fig 2) indicating prolongation of the IRP for any given BP Patients with MS and CMO had a short IRP for their blood pressure

IRP increased slightly with increasing heart rate in normal subjects ($r = 0\ 50$ ns) (Fig 3) one patient disturbed the statistical relationship

Multiple regression analysis correlating IRP with aortic closing pressure (AoCP) and heart rate (HR) in normal subjects greatly improved the correlation coefficient ($R = 0\ 85$ $p < 0\ 001$) compared with the correlation coefficients for each of these variables taken independently and provided the following equation for predicted IRP

$$IRP = 0.97\ AoCP + 0\ 62\ HR - 86\ 6$$

Using this equation the deviation of the measured IRP from predicted normal (ΔIRP) was calculated in each patient The mean ΔIRP for each patient group is given in Table IV Measured IRP was prolonged in HOCM and AI ($+\Delta IRP$) was short in CMO and MS ($-\Delta IRP$) and normal in hypertension and CAD although there was considerable individual variation in each group so that the standard deviations were high

DE time The DE time measured 58 ± 17 msec in normal subjects It was normal in hypertension in CAD (all groups) in CMO AS and AI and was prolonged in HOCM ($p < 0\ 05$) and was shortened in MS ($p < 0\ 01$)

A_2 E point The duration A_2–E point was 116 ± 13 msec in normal subjects (Table II) It was prolonged in hypertension ($p < 0\ 01$) aortic stenosis (ns) and aortic incompetence ($p < 0\ 01$) and was greatly increased in HOCM ($p < 0\ 001$) In CAD the A_2–E point time was increased especially in patients with normal systolic function (% $\Delta S > 25\%$) ($p < 0\ 001$) The A_2–E point time was slightly shortened in CMO (ns) and was greatly shortened in MS ($p < 0\ 001$) There was

mitral incompetence Group 1 echocardiograms showed great LV enlargement (Dd 6.3 ± 0.6 $p < 0.001$) and a low % ΔS ($p < 0.001$) Sinus tachycardia was present The single patient in group 2 (normal IRP) also had severe left ventricular enlargement and LV dysfunction but was hypertensive this may have increased his IRP so that it was not shortened as in the other patients with severe LV dilatation and LV dysfunction In contrast patients in group 3 (prolonged IRP) had mild LV enlargement (Dd 5.6 ± 0.4 $p > 0.05$) and a slightly decreased LV shortening fraction (mean % ΔS 27 ± 12 $p < 0.05$) although eight patients in group 3 had suffered previous infarction with regional ventricular asynergy and three had mild or trivial functional mitral incompetence LV end diastolic pressure (25 ± 10 mm Hg) was increased less than in group 1 (40 ± 6 mm Hg)

Relation of IRP to systemic blood pressure and

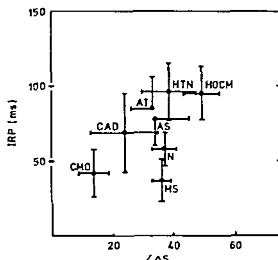

Fig 6 Systolic shortening fraction *(% ΔS)* and isovolumic relaxation period *(IRP)* in normal subjects *(N)* and in different cardiac diseases % ΔS and IRP increased or decreased in parallel, except in mitral stenosis *(MS)* where IRP was markedly shortened

different cardiac diseases are shown in Fig 5 In hypertension HOCM AI and AS IRP increased with no or little change in ICT in MS both IRP and ICT were short while in CMO IRP was short and ICT was prolonged

2 LV shortening fraction (% ΔS) IRP was related to percentage shortening of the LV in systole (Fig 6) In general in diseases where % ΔS was high IRP was prolonged patients who had a lower % ΔS had a shorter IRP In MS IRP was short for the % ΔS

Discussion

Echocardiography permits accurate measurement of the true isovolumic relaxation period of the left ventricle Our values for IRP (58 ± 11 msec) are shorter than those of most previous studies which used older methods to mark the end of the IRP invasive cardiac catheterization[6] angiographic studies the O point of the apexcardiogram and phono Doppler measurements[16] A previous echocardiographic study used the onset of rapid opening of the anterior mitral leaflet to mark the end of the IRP[17 18] We measured IRP from aortic closure to the point of separation of the mitral leaflets on the echocardiogram we believe that the point of separation of the leaflets is less ambiguous and conceptually more correct as a marker of the end of the true IRP Echocardiography also permits measurement of the mitral valve opening time DE and the time A_2—maximum mitral opening (E point)[1] a

measurement previously possible only in patien with mitral stenosis and an opening snap or with a prosthetic mitral valve producing an audible opening click

Isovolumic relaxation period is the time interval from aortic valve closure to mitral opening and depends on the aortic closing pressure the height of the v wave in the left atrium (mitral opening pressure) and the rate of pressure fall in the left ventricle (Fig 7) IRP may also be heart rate dependent and tends to increase in normal subjects with increasing heart rate In contrast to previous work using older methods for measuring IRP[14] our study shows an important relation to systemic blood pressure in normal subjects and use of the multiple regression analysis (correcting for heart rate and blood pressure) improved the relationship significantly Multiple regression analysis provided us with an equation for predicting IRP which may be useful in assessing isovolumic relaxation time in cardiac disease We did not measure left atrial pressure but IRP is very short in mitral stenosis and especially short in patients with CAD and important additional functional mitral incompetence The rate of LV pressure fall in early diastole (i e early diastolic relaxation of the LV) is also a determinant of IRP the greatly increased IRP and ΔIRP observed in patents with HOCM and the increase in IRP in patients with AS may be due to the mechanism, since both diseases are associated with high LV chamber stiffness as a consequence of severe LVH[5 2 2] In systemic hypertension the long IRP is probably the result of the increased aortic pressure in most patients since mean ΔIRP is normal in some patients there may also be a change in LV chamber compliance due to ventricular hypertrophy Systemic blood pre-

$p < 0.05$, $p < 0.01$, $p < 0.001$ } Compared to the normal group

an over all linear relationship between IRP and A–E ($r = 0.87$ $p < 0.001$)

Other echocardiographic measurements related to LV compliance The *mitral EF slope* was decreased in hypertension ($p < 0.001$) aortic stenosis ($p < 0.05$) and aortic incompetence ($p < 0.01$) and was greatly decreased in HOCM ($p < 0.001$) It was also decreased ($p < 0.05$) in the six patients with CAD who had normal LV function (% ΔS > 25%) but was not different from normal when the whole CAD group was examined together The EF slope tended to increase in CMO although the difference was not statistically significant The inverse relation between IRP and the mitral EF slope in different diseases is shown in Fig 4*A* Diseases associated with a prolonged IRP had a reduced mitral EF slope in CMO IRP was short and the EF slope increased In MS both IRP and the mitral EF slope were very short The relation between IRP and EF slope tended to be positive however within the group of normal subjects (Fig 4*B*) and was positive or unrelated within the other disease states

The *PR AC time* was 70 ± 7 msec in normal subjects It was normal in AS AI and HOCM and slightly decreased in hypertension (ns) The PR–AC time was short in the nine patients with CAD who had a decreased shortening fraction ($p < 0.001$) There was no relation between the PR–AC time and IRP

Relation between IRP and measurements of systolic LV performance

1 Isovolumic contraction time ICT was 38 ± 22 msec in normal subjects it was shortened in AI and MS and increased in CMO the differences did not reach statistical significance because the number of patients in which the measurement could be made accurately was small The mean values for ICT and IRP in

Other simple echocardiographic measurements which have been related to LV compliance include the mitral EF slope and the PR–AC time The mitral EF slope is related to early diastolic filling and in the absence of mitral stenosis to early diastolic compliance [3] IRP and the A–E point time measure a similar phenomenon to the EF slope—the rate of LV relaxation and filling in early diastole—and were related to the mitral EF slope The three measurements do not examine precisely the same period in diastole however studies of LV relaxation and compliance should define very carefully the exact period of diastole to which they refer since the diastolic pressure volume and stress strain relations change throughout diastole [4] The PR AC time is a very rough and not constant measurement of end-diastolic compliance a long AC time (short PR AC) indicating a high LV end diastolic pressure [7] there was no relation between the PR AC time and true IRP which measures LV function in early diastole

There was a positive relationship between systolic LV shortening (% ΔS) and the duration of the IRP in different cardiac diseases In HOCM % ΔS was increased and IRP greatly prolonged while in CMO % ΔS was reduced and IRP was short Patients with increased contractility may have an increased intracellular Ca and this may prolong early diastolic relaxation an active process dependent on the Ca reuptake mechanisms increased systolic tension may therefore be associated with greater residual tension during early diastole and a prolonged IRP We did not make serial studies of the effects of positive and negative inotropic intervention in the same patients however and can provide no further information relating to these changes Similarly the relationship between ICT and IRP was not clear in our study although hemodynamic studies have shown that peak negative dp/dt is related to peak positive dp/dt

Summary

Isovolumic relaxation period (IRP) was measured noninvasively from the onset of the aortic component of the second heart sound on the phonocardiogram to the point of separation of the mitral leaflets on the echocardiogram IRP was measured in 83 patients 10 normal subjects and 73 patients with different cardiac diseases The duration of IRP was 58 ± 11 msec in normal subjects It was prolonged in hypertension ($p < 0.001$) HOCM ($p < 0.001$) aortic stenosis ($p < 0.05$) and aortic incompetence ($p < 0.01$), and was shortened in congestive cardiomyopathy ($p < 0.05$) and mitral stenosis ($p < 0.01$) In patients with coronary artery disease and normal overall systolic LV function IRP was prolonged ($p < 0.001$) IRP was shortened in four patients with coronary disease who had severe LV dysfunction and severe additional mitral incompetence

IRP was related to systemic blood pressure percentage shortening of the LV in systole and to the mitral EF slope It tended to increase with increasing heart rate and a regression equation was developed for predicting IRP in relation to blood pressure and heart rate in normal subjects There was no relation to the PR AC time or to isovolumic contraction time IRP is a useful measurement of LV dynamics in early diastole

sure and heart rate are easy to measure at the bedside however and can be taken into account when assessing measurements of IRP in different cardiac diseases

IRP is prolonged in most patients with coronary artery disease especially in those in whom over all LV contraction as measured by % ΔS is normal IRP was prolonged in all but one patient but mean ΔIRP was essentially normal since one patient in the group had a very low ΔIRP (−48 msec) These data confirm previous studies[9, 17] and probably correspond to the decreased peak negative dp/dt in patients with myocardial ischemia[1] The increased IRP may also be related to asynchronous relaxation of different regions of the myocardium[3] (Fig 7) It is interesting that patients with severe extensive LV dysfunction and functional mitral incompetence have a short IRP Mean ΔIRP was again almost normal since one patient had a prolonged corrected IRP but ΔIRP was short in the other patients in the subset confirming a real shortening of the duration of isovolumic relaxation The findings in these patients are similar to those of congestive cardiomyopathy where the large dilated left ventricle may have increased operative chamber compliance at operative volume in early diastole The rapid mitral EF slope supports this concept although a high LA pressure and high LA v wave may contribute to the shortened IRP *in patients with severe LV dysfunction and* important functional mitral incompetence

Aortic incompetence was associated with a prolonged IRP and ΔIRP There is no true isovolumic relaxation period in aortic incompetence and ventricular filling commences immediately with *the onset* of ventricular *relaxation* retrograde ventricular fillig may delay the onset of mitral valve opening although there may also be a decrease in LV chamber compliance because of ventricular hypertrophy and volume overload which further prolongs measured IRP

The DE time was normal in all groups of patients except those with HOCM who had a prolonged DE time and the A_2–E point time which increased *in general in parallel* with the increase in true IRP was longest in patients with HOCM The great increase in DE time in HOCM may be related to the severe LVH and decreased chamber compliance which occurs in severe LV hypertrophy It is noteworthy that the DE time was not prolonged in hypertension emphasizing

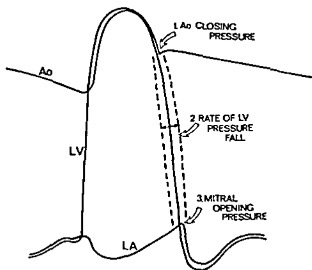

Fig 7 Diagrammatic left ventricular *(LV)* aortic *(Ao)* and left atrial *(LA)* pressure pulse tracings Isovolumic relaxation period (IRP) depends on (1) aortic closing pressure (2) rate of fall of LV pressure and (3) mitral opening pressure The rate of fall of LV pressure may be the resultant of regional asynchrony in ventricular relaxation in patients with cardiac diseases

again the importance of the high aortic pressure rather than the LV hypertrophy in the prolongation of IRP in hypertensive patients The mean DE time was also not prolonged in coronary artery disease It seems that changes in regional muscle stiffness due to fibrosis (CAD) or mild *to moderate LVH and moderate changes in LV* chamber stiffness (hypertension AS) are not sufficient to affect mitral valve opening once this has started it is only in patients with severely abnormal chamber stiffness due to unusual LV hypertrophy and geometrical changes within the *ventricle (e g HOCM) that there is prolongation* of the mitral valve opening time DE

The study also provides information in relation to the A_2–E point (A –OS time) in normal subjects and in patients with mitral stenosis[6, 2] Measurement of true IRP is a better measurement of the severity of MS than total time A_2–OS since mitral valve thickening and rigidity may prolong the DE time in some patients with severe MS to offset the extreme *shortening of true* IRP in patients with severe disease The normal A –E point time is 116 ± 13 msec There is a decrease in A –OS time in MS but we did not subdivide patients with MS further since not all patients with mitral stenosis underwent cardiac catheterization

The relationship of pulmonary artery wedge pressure to the posterior aortic wall echocardiogram in patients free of obstructive mitral valve disease

Alan G Wasserman, M D
Jerry F Meyer M D F A C C
Allan M Ross M D F A C C
Washington D C

Numerous investigations have been designed to uncover reliable echocardiographic measurements which reflect human left ventricular compliance Since decreased left ventricular compliance will be reflected in an increased left ventricular filling or pulmonary artery wedge pressure a noninvasive method to assess this pressure would have widespread clinical utility

Based upon echocardiographic measurements it has been proposed that characteristic aortic wall motion represents left atrial filling and emptying events [3] Resistance to left atrial emptying was estimated by Strunk and colleagues using the fraction of passive posterior aortic wall motion occurring in the first third of diastole (atrial emptying index AEI) In that study patients had fixed mitral valve obstruction as the cause of prolonged left atrial emptying

The purpose of this study was to evaluate the relationship of this index (AEI) to left ventricular filling pressures in patients free of mitral valve obstruction which in such patients is primarily related to differences in left ventricular compliance

Materials and methods

Twenty five consecutive unselected patients requiring hemodynamic evaluation had M mode echocardiography performed at the time of left ventricular filling pressure (pulmonary capillary wedge) measurement Data from six patients were rejected four because of suboptimal echocardiograms and two because of evidence of mitral stenosis Two patients were studied twice, one after a change in heart rhythm and the other after treatment with vasodilators for a total of 21 studies in 19 patients Studies were performed after informed consent was obtained There were eight women and 11 men with a mean age of 53 years (range 30 to 74 years) The final diagnosis was coronary artery disease in 14 patients, congestive cardiomyopathy in two and three patients were judged to be normal

Echocardiograms were made using a 2.25 MHz transducer placed along the left sternal border in the third or fourth intercostal space and rotated until elements of aortic leaflets were seen within the aortic root The image of the aortic root was expanded to the maximum recording scale in order to facilitate measurements All aortic measurements were made in that part of the recording showing maximal total aortic root excursion

The method described by Strunk and associates[4] and by Lewis and colleagues[3] for determining the atrial emptying index was employed For patients in sinus rhythm posterior aortic wall motion reflecting passive left ventricular filling is from points O to A (Fig 1) The point where the posterior aortic wall begins its posterior motion is O and the A point describes a second abrupt posterior movement caused by atrial contraction. The left atrial emptying index (X/OA) is the ratio of the posterior aortic wall motion occurring in

Abbreviations AEI = atrial emptying index AF = atrial fibrillation CAD = coronary artery disease CM = cardiomyopathy J = junctional rhythm N = normal PAWP = pulmonary artery wedge pressure S = sinus rhythm TAE = total aortic excursion

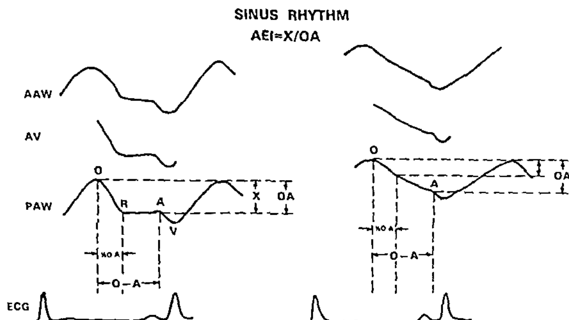

Fig 1 Schematic drawing illustrating the calculation of the atrial emptying index (*AEI*) for patients in sinus rhythm *Left* AEI = X/OA ≈ 1 0 *Right* AEI = X/OA < 1 0 I assive atrial emptying occurs between points *O* and *A* Abbreviations *AAW* = anterior aortic wall *AV* = aortic valve *PAW* = posterior aortic wall

the first third of this passive emptying period (X) to the total passive emptying (OA) For patients in atrial fibrillation the end of the passive dias tole is taken as the onset of ventricular systole Point V on the posterior aortic wall echocardio gram corresponds to the end of the QRS complex on the electrocardiogram The atrial emptying index is again the ratio of the motion occurring during the first third of this period (X) to the total passive emptying (OV)

The anterior posterior excursion of the aortic root was measured using only the leading edge of the posterior aortic wall echo and averaged over five cycles Linear regression equations and corre lation coefficients were calculated and group comparisons were made using Student s unpaired t test

Results

There were 12 patients with normal hemody namics (group A filling pressure ≤ 12 mm Hg), and seven patients (nine studies) with abnormal hemodynamics (group B filling pressure > 12 mm Hg) (Table I) Of the 12 patients in group A 11 were in sinus rhythm and one in a junctional rhythm For group B four were in sinus rhythm two in atrial fibrillation (one studied twice) and one patient was studied first in a junctional rhythm and then after conversion to sinus rhythm The mean pulmonary wedge pressures for groups A and B were 6 9 ± 1 7 mm Hg (mean ± S D) and 23 6 ± 6 9 mm Hg respec tively ($p < 0 01$)

Figs 2 and 3 demonstrate normal and abnor mal AEI s respectively The mean atrial empty ing index for Group A was 0 94 ± 0 06 and for group B it was 0 61 ± 0 02 ($p < 0 001$) (Fig 4) There was a significant ($p < 0 001$) negative cor relation between pulmonary artery wedge pres sure and the AEI r = −0 91 Mean heart rate for group A was 74 beats/minute compared to 89 beats/minute in group B ($p < 0 05$) Because of the potential influence of heart rate on the left atrial emptying pattern and because of the differ ences in heart rate in our two groups we investi gated the possibility that the differences observed in the AEI were secondary only to rate Normal ization for heart rate was accomplished by divid ing the AEI by $\sqrt{RR}$ A significant ($p < 0 001$) correlation remained with an r value of −0 85 (Fig 5)

No patient in the normal group had an atrial emptying index below 0 80 and no patient in group B with a pulmonary wedge pressure greater

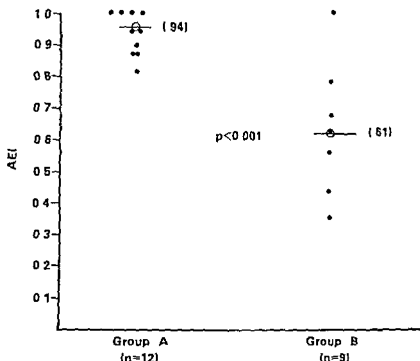

Fig 4 The atrial emptying index (*AEI*) in patients with normal (group A PAWP ≤ 12 mm Hg) and abnormal (group B PAWP > 12 mm Hg) pulmonary artery wedge pressures *P* = probability

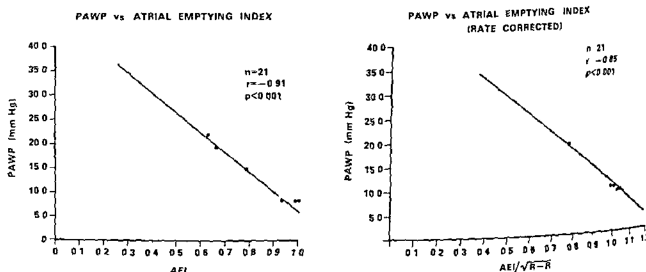

Fig 5 Pulmonary artery wedge pressure (*PAWP*) plotted against the atrial emptying index (*AEI*) *Left* before and *right* after rate correction There is a high degree of negative correlation both before (r = -0 91) and after (r = -0 85) rate correction p = probability

root excursion in patients with valvular heart disease and found a statistically significant decrease in motion in patients with mitral stenosis and a statistically significant increase in motion in patients with mitral regurgitation as compared to a normal population They found no significant difference in patients with aortic regurgitation as compared to the normal population We did not include data from patients wit significant valvular disease but recognize th possibility that markedly increased aortic com pliance or altered left atrial filling and emptyr secondary to severe mitral regurgitation ma alter these correlations

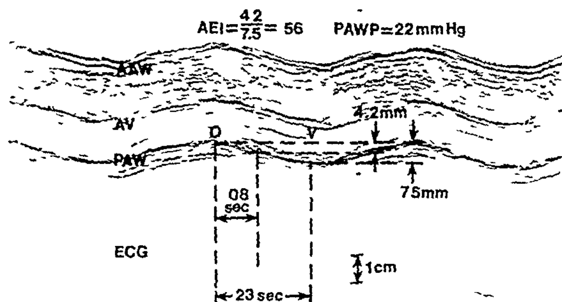

Fig 3 Aortic echocardiogram and measurement of atrial emptying index (AEI) from a patient with an elevated pulmonary artery wedge pressure (PAWP) Abbreviations same as in Fig 1

than 18 mm Hg had an atrial emptying index greater than 0.66

The total aortic root excursion for groups A and B were 9.2 ± 1.9 mm and 6.0 ± 2.4 mm ($p < 0.01$) respectively. When the total aortic root excursion was related to the pulmonary wedge pressure for the total population there was a very weak correlation with an r value of −0.46 ($p < 0.04$) which did not improve after normalizing for rate

Discussion

Previous attempts to establish echocardiographic determinants of left ventricular pressure and compliance have concentrated on the mitral valve echocardiogram. Konecke and co workers[6] reported that the echocardiographic pattern of mitral valve motion is altered in patients with markedly elevated left ventricular diastolic pressure. They found that a PR AC interval of 0.06 sec or less as derived from the electrocardiogram and mitral valve echocardiogram correlated with an elevated left ventricular end diastolic pressure (≥ 20 mm Hg) when the atrial component of the left ventricular pressure pulse is at least 8 mm Hg. A recent report by Lewis and co workers did not substantiate the reliability of this measurement either in the resting or the dynamic state

It has been suggested that the mitral E F slope may be a function of left ventricular compliance.[7,8] A decrease in the diastolic closure rate of the mitral valve a constant finding in mitral stenosis has also been reported in conditions without mitral valve pathology but with impaired left ventricular filling. DeMaria and co workers established a correlation between transmitral flow in the first third of diastole and the E F slope ($r = 0.87$) and although the mitral E F slope did not correlate closely with compliance they found that ventricular compliance was generally reduced in patients with an early mitral diastolic closing velocity of less than 75 mm/second. Vignola and associates[9] demonstrated that the pressure/volume relationship in the left ventricle in early diastole is an important determinant of the mitral E F slope

Although the echocardiographically observed aortic root motion may be the result of many factors including aortic compliance, Strunk and co workers and Akgun and colleagues presented data supporting the hypothesis that aortic wall motion is governed mainly by the rate of left atrial volume changes. The posteriorly directed aortic wall motion during ventricular diastole would then be secondary to the rate of left atrial emptying. Mechanical obstruction to flow of blood at the level of the mitral valve alters the pattern of left atrial emptying and Strunk and co workers[4] quantified the degree of obstruction with the echocardiographically measured atrial emptying index

Akgun and associates[11] also compared aortic

Ischemic cardiomyopathy: A clinicopathologic study of fourteen patients

Edward H. Schuster, M.D.
Bernadine H. Bulkley, M.D.
Baltimore, Md.

A cardiomyopathy due to coronary artery disease is a relatively new concept first proposed in 1969.[1] In 1970 Burch and co-workers[2] coined the term "ischemic cardiomyopathy" for those patients with coronary artery disease, enlarged hearts, and the clinical manifestations of a congestive cardiomyopathy. Since that time, further information has been obtained from natural history[3, 4] and cardiac catheterization[5] studies of patients with ischemic cardiomyopathy. The term "ischemic cardiomyopathy" has been broadened by some to include any patient with coronary disease and a decreased left ventricular ejection fraction regardless of symptoms or heart size.[3] In order to define a morphological explanation for ischemic cardiomyopathy, we studied 14 autopsied patients who met the clinical criteria for ischemic cardiomyopathy. At autopsy these patients had severe coronary artery disease with injury in multiple vascular distributions. Although the hearts were dilated and hypertrophied, the myocardial walls were disproportionately thinned, suggesting inadequate myocardial thickness for the degree of dilatation. The latter may be a factor contributing to the diffuse inadequacy of myocardial function in a disease of regional injury.

Materials and methods

Patients from the autopsy files of The Johns Hopkins Hospital were included in this study if they met the clinical definition of this entity[4] including significant (> 75%) coronary narrowing in at least one vessel, a longstanding clinical history of congestive heart failure, cardiomegaly, and if the hearts had been routinely processed at autopsy with postmortem coronary arteriography and fixation of the heart in formalin in an intact distended state. Patients were excluded if (1) there was a history of hypertension or alcohol abuse, (2) there was evidence of primary valvular disease, congenital heart disease, or ventricular aneurysm formation, or (3) there was evidence of other etiologies of cardiomyopathy (sarcoid, amyloid, hypertrophic cardiomyopathy, etc.). Over 200 consecutive autopsy cases with coronary artery disease whose hearts had been similarly processed at autopsy were reviewed and 14 met the above clinical criteria for inclusion in this study. The patient's clinical records were studied and coronary risk factors, electrocardiograms, and chest radiographics were reviewed and tabulated.

At autopsy, all hearts were prepared by postmortem angiography utilizing injection of a gelatin pigment barium mass at pressures of 100 to 150 mm Hg controlled by manometer and subsequently fixed in formalin in a distended state. Sets of stereoscopic radiographs were prepared of the intact heart and its transverse sections. The hearts were studied grossly and histologically for the presence of myocardial lesions and obstructive disease of the coronary arteries. The hearts were serially sliced and transverse sections were subjected to planimetry denoting areas of remote and recent myocardial necrosis. Each transverse slice was weighed minus the right ventricle. Using a digitizing computer (Hewlett Packard), the grams of infarcted tissue and the percent of left ventricle infarcted was obtained.

with stroke volume or stroke index [13,14] but has not been characterized as a function of left ventricular diastolic hemodynamics Burggraf and colleagues [2] looking at total aortic root systolic anteroposterior motion found that a value < 7 mm indicated poor left ventricular performance although they did not find it to be a predictor of abnormal left ventricular end diastolic pressure We found only a very weak correlation between total aortic root excursion and mean pulmonary artery wedge pressure but the mean total excursion for those patients with pulmonary wedge pressures > 12 mm Hg was 6 0 ± 2 4 mm Although there was considerable overlap of values this was significantly ($p < 0.01$) lower than those patients with wedge pressures ≤ 12 mm Hg whose excursion was 9 2 ± 1 9 mm

The results of this study indicate that the atrial emptying index provides a noninvasive measure of left ventricular filling pressures in a diverse group of patients This relationship is not limited to patients with obstructive mitral valve disease and therefore may have more general clinical utility

Summary

Aortic wall echocardiograms were obtained simultaneously with pulmonary artery wedge pressures (PAWP) in 21 patients free of obstructive mitral valve disease There was a significant ($p < 0.001$) negative correlation between the fraction of passive posterior aortic wall motion occurring in the first third of diastole (the atrial emptying index—AEI) and the pulmonary artery wedge pressure ($r = -0.91$) The AEI for patients with normal PAWP (≤ 12 mm Hg) was 0 94 ± 0 06 (mean ± S D) compared with 0 61 ± 0 20 for those with abnormal PAWP (> 12 mm Hg) No patient with a normal PAWP had an AEI < 0 80 and no patient with a PAWP > 18 mm Hg had an AEI > 0 66 These data suggest that analogous to the reported use of the AEI to estimate severity of mitral obstruction the index provides a noninvasive measure of left ventricular filling pressure when the mitral valve is normal

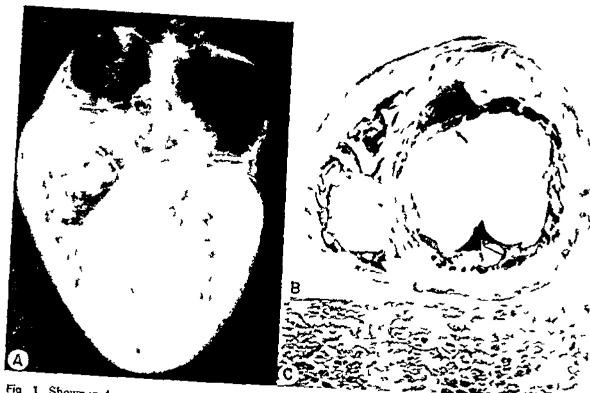

Fig 1 Shown in *A* is a postmortem angiogram of a patient with ischemic cardiomyopathy The heart is diffusely dilated the walls are thinned and severe coronary occlusive disease is present A transverse section through both right and left ventricles is shown in *B* Subendocardial infarcts are present anteriorly laterally posteriorly and a transmural infarct is present in the septum A mural thrombus overlays the anteroseptal infarct (arrow) All infarcts were healed (*C*) showing well formed fibrous tissue (Hematoxylin and eosin original magnification ×200)

measured only at points without gross and histological evidence of necrosis or fibrosis were as follows anterior 1 2 cm ± 0 1 lateral 1 1 cm ± 0 1 posterior 1 1 cm ± 0 2 and septal 1 1 cm ± 0 1 These wall thickness measurements were compared with those of patients who died from recurrent infarctions without a clinical diagnosis of ischemic cardiomyopathy (Table III) and with those of patients with primary valvular insufficiency and primary myocardial disease The mean anterior posterior lateral and septal wall thickness as well as the total average wall thickness for the group with ischemic cardiomyopathy was significantly thinner than the wall thickness of patients with recurrent infarctions valvular insufficiency or primary myocardial disease ($p < 0\ 01$ unpaired t test)

Examination of the coronary tree in the 14 patients with ischemic cardiomyopathy revealed multiple vessel involvement by atherosclerosis in all patients In sev r patients three major vessels were narrowed 7 nd in seven patients two vessel involvement was present (average 2.5 major coronary ar es) None of the patients had significant left main disease and all of the patients had well developed collaterals visible by postmortem angiogram (Fig 2) Of the 14 patients seven (50%) had infarcted or scarred papillary muscles and seven (50%) had mural thrombi By gross and histological evaluation one patient had only one remote myocardial infarction but one which involved 50% of the left ventricular circumference Seven had two infarcts four had three infarcts and two had four infarcts all involving at least two vascular distributions Of the 14 patients 12 had anterior infarctions (four transmural eight subendocardial) nine had posterior infarctions (one transmural eight subendocardial) and eight had lateral infarctions (three transmural five subendocardial)

The amount of infarcted myocardium determined by planimetry ranged from 8% to 46% (average 25%) In only four patients (28%) was more than 30% of the left ventricle involved, and in four patients less than 20% of the myocardium was infarcted Histologic examination showed well formed myocardial scars in all hearts. In the

Table I Clinical findings

Number of patients	14
Age	40-81 (avg 62 yrs)
Sex	3 females (21%) 11 males (85%)
Diabetes	3 (21%)
Hypercholesterolemia	3 (21%)
Myocardial infarction	8 (64%)
Angina pectoris	6 (42%)
Congestive heart failure	14 (100%)
Electrocardiogram	
Remote myocardial infarction	5 (36%)
Acute myocardial infarction	2 (14%)
Conduction disturbances	7 (50%)
Atrial arrhythmias	3 (21%)
Ventricular arrhythmias	7 (50%)
Chest radiograph	
Cardiomegaly	14 (100%)
Increased pulmonary vascularity	3 (21%)
Pulmonary edema	6 (42%)

To compare ventricular wall thickness and over all topography 12 patients who died from recurrent myocardial infarctions 16 patients with chronic primary valvular insufficiency (eight mitral regurgitation eight aortic regurgitation) and 16 patients with primary congestive cardio myopathy were selected from the autopsy files

Results

Of over 200 cases studied 14 were identified which fulfilled the clinical criteria for ischemic cardiomyopathy

Clinical findings The clinical data of the 14 patients are summarized in Table I The patients ranged in age from 40 to 81 years (average 62 years) with 11 of 14 being male None of the patients had a history of hypertension or alcohol abuse Of the 14 patients three had diabetes mellitus (21%) and three had hypercholesterol emia (21%) Nine patients (64%) sustained a remote myocardial infarction by history six patients (42%) had angina pectoris and all 14 had longstanding symptoms of severe intractable congestive heart failure In none of the 14 patients were the electrocardiograms normal but in only half of the patients were the changes diagnostic for myocardial infarction The electro cardiogram revealed remote myocardial infarc tion in five patients (36%) and acute infarction in two (14%) Conduction disturbances were fre quent in these patients three (21%) had a left bundle branch block two (14%) a right bundle branch block and two had a left anterior hemiblock Three of the patients were in atrial fibrillation and three had recurrent episodes of ventricular tachycardia Cardiomegaly on chest radiograph was noted in all patients and nine patients (64%) had radiographic evidence of con gestive heart failure at their most recent exami nation

Table II Causes of death

	No of patients and %
Ventricular tachycardia/ventricular fibrillation	7 (50%)
Hypotension	2 (14%)
Acute myocardial infarction	1 (7%)
Intractable heart failure	4 (29%)

The immediate causes of death of the patients are shown in Table II Seven patients (50%) died suddenly of documented ventricular arrhythmias two (14%) from hypotension one from an acute myocardial infarction and four (28%) from intractable heart failure

Autopsy findings The average heart weight was 625 grams with a range of 450 to 830 grams. All the hearts had biventricular dilatation with no evidence of discrete aneurysm formation (Figs 1 and 2) Although the average total heart weight (625 grams) and the average left ventricular weight (290 grams) were above normal and indi cative of cardiac enlargement the maximal left ventricular wall thickness was not increased The average maximal left ventricular wall thickness

Fig 3 Shown here are a postmortem angiogram (*A*) and a gross specimen (*B*) of a heart with an anteroseptal aneurysm of the left ventricle Although the infarct is large and the coronary disease severe in contrast to ischemic myocardiopathy the heart here shows marked regional wall dilatation rather than a diffuse myocardiopathic type of dilatation. Thrombus is layered within the aneurysm (*arrows*)

tion[6] We have been able to identify only three reports describing autopsy findings in ischemic cardiomyopathy [3, 6, 11] and in only three patients were the studies detailed What distinguished the heart in ischemic cardiomyopathy from the heart of patients with prior infarctions and no evidence of left ventricular dysfunction remained unclear In this study of 14 autopsied patients with ischemic cardiomyopathy we examined several possible determinants of the diffuse left ventricular dysfunction including severity and extent of coronary disease total amount of left ventricle injured by old and new infarction heart size and wall thickness

As observed by others from clinical studies[1] a prominent feature of these patients was the severity of their coronary disease All had critical narrowings in at least two major coronary arteries and multiple lesions within at least one of these major vessels Half of the patients had > 75% narrowing in all three major vessels Severe coronary disease alone is not sufficient however to cause ischemic cardiomyopathy Most patients with coronary artery disease with and without infarction do not have congestive heart failure

All the hearts studied here with ischemic cardiomyopathy had grossly evident myocardial infarction Although one might surmise that the size of the infarction is a major determinant of ischemic cardiomyopathy as it has shown to be for cardiogenic shock[12] findings here suggest that the multiple sites of injury rather than the extent of the injury may be more important Our patients showed as little as 8% and as much as 46% of the left ventricle involved by infarction with an average of 25% infarction for the group Of the 14 patients four had less than 20% of their myocardium lost by old or new infarction In 13 of the 14 patients however infarcts were multiple

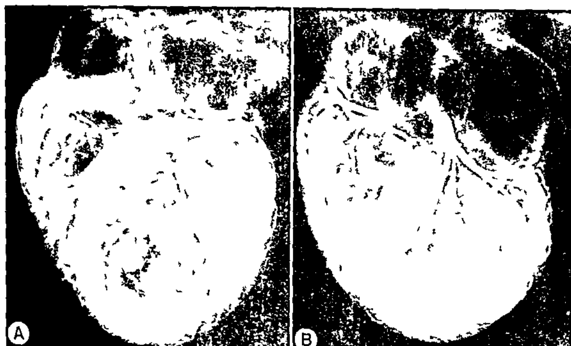

Fig 2 Postmortem angiogram from another patient with ischemic cardiomyopathy (*A*) again showing a globular diffusely dilated heart that has a similar shape to the heart in primary dilated cardiomyopathy an example of which is shown in *B* The coronary arteries in *A* are severely diseased but in *B* they are normal.

there was evidence of recent infarction as well but in each the recent infarcts were small involving less than 10% of the left ventricular wall The non infarcted myocardium histologically revealed focal myocardial cell hypertrophy foci of interstitial and perivascular fibrosis but no other evident or characteristic abnormality

Discussion

In 1969 Raftery and associates[1] reported four patients with a congestive cardiomyopathy who at catheterization had severe three vessel coronary artery disease They concluded that chronic ischemic heart disease could present as a cardiomyopathy and that before a diagnosis of primary congestive cardiomyopathy is made occlusive coronary disease must be excluded In 1970 Burch and colleagues[2] coined the term ischemic cardiomyopathy for those patients with coronary artery disease and severe ventricular dysfunction Two autopsied patients were studied who had focal fibrosis ventricular hypertrophy and ventricular dilatation Dash and co workers[3] presented their findings of 30 patients who had congestive heart failure and at cardiac catheterization had coronary artery disease decreased left ventricular ejection fraction (< 0 48) and widespread left ventricular wall motion abnormalities

In this study 14 autopsied patients with ischemic cardiomyopathy were studied Clinically all patients had heart failure with cardiomegaly and none had a history of hypertension or chronic alcoholism Although all patients had pathologic evidence of severe coronary artery disease and infarction only 64% had a history of myocardial infarction and only 42% had angina pectoris Two patients (14%) did not have a history of angina pectoris or myocardial infarction Furthermore in three patients the presence of bundle branch block on the electrocardiogram and the lack of a clear cut history of myocardial infarction led to a clinical diagnosis of primary myocardial disease One of the most striking electrocardiographic abnormalities in these patients was the frequency of ventricular dysrhythmias Eight patients had a history of recurrent ventricular ectopic beats and three had prior documented ventricular tachycardia or ventricular fibrillation

These clinical features of ischemic cardiomyopathy are compatible with the reports of others[1-4] What has received little attention however are the pathologic features of the heart in this condi

hypertrophy is a reflection of the intrinsic idiopathic myocardiopathic process in ischemic cardiomyopathy it seems likely that the severity of coronary disease and the limitations in blood supply combined with multifocal myocardial scarring limit the ability of the wall to respond appropriately to the demands of increased wall tension secondary to cavity dilatation

Summary

Ischemic cardiomyopathy has been defined clinically as congestive heart failure occurring in patients with coronary artery disease without coexisting hypertension primary valvular disease ventricular aneurysm formation or known causes of cardiomyopathy Morphologic definition of this entity is scarce We reviewed over 200 patients with coronary artery disease who came to autopsy at this hospital and identified 14 who met the above criteria At autopsy all the hearts showed diffuse biventricular dilatation without aneurysm formation All had evidence of recurrent infarction in more than one vascular distribution and postmortem angiography revealed extensive coronary artery disease The amount of infarcted myocardium determined by planimetry ranged from 8% to 46% Although the hearts were enlarged with an average weight of 600 grams the non infarcted ventricular myocardium was thinner than seen in normals in patients with ischemic heart disease without cardiomyopathy in patients with idiopathic congestive cardiomyopathy and in those with dilatation due to valvular regurgitation The results suggest that ischemic cardiomyopathy does not merely reflect a critical amount of myocardium lost but rather severe diffuse coronary artery disease accompanied by multiple sites of infarction which together lead to progressive dilatation disproportionate wall thinning and inadequate compensatory wall thickening Thus these patients appear to have a true cardiomyopathy in that the entire left ventricle (infarcted and non infarcted tissue) appears to be adversely affected by the ischemic process insofar as there is a diffuse globular remodeling of the heart

Table III Ventricular wall thickness of non infarcted myocardium

	Group I — Ischemic cardio myopathy	Group II— Recurrent infarctions	Group III— Primary valvular insufficiency (aortic or mitral insufficiency)	Group IV — Idiopathic dilated cardiomyopathy
nterior wall thickness (mean)	1 20 cm (±0 10)	1 7 cm (±0 10)	1 9 cm (±0 10)	1 7 cm (±0 10)
osterior wall thickness (mean)	1 10 cm (±0 20)	1 7 cm (+0 11)	1 9 cm (±0 10)	1 6 cm (±0 10)
ateral wall thickness (mean)	1 10 cm (±0 10)	1 7 cm (±0 11)	2 0 cm (±0 10)	1 7 cm (±0 10)
eptal wall thickness (mean)	1 10 cm (±0 10)	1 6 cm (+0 07)	1 9 cm (±0 10)	1 6 cm (±0 10)

Group I measurements w re significantly less than those in the oth r three groups ($p < 0 01$)

nd were in the distribution of more than one najor coronary artery It appears that when the ntire loss of myocardium is in one vascular listribution the area of regional injury shows naximal dysfunction and the non infarcted nyocardium undergoes compensatory wall thick ning If cardiac dilatation occurs it is apt to be egional or aneurysmal If the injury occurs in nultiple vessel distribution in the setting of extensive coronary disease diffuse rather than egional dilatation is apt to occur That such lysfunction and diffuse dilatation can occur with is little as 20% loss of left ventricle might suggest hat diffuse ischemia combined with multisite njury might contribute to the progressive cardiac lilatation of ischemic myocardiopathy

What is perhaps one of the most striking feature of the heart in ischemic myocardiopathy is that it takes on the over all globular configura tion of a dilated congestive cardiomyopathic heart (Fig 2) a configuration to be readily distin guished from the heart with discrete left ventric ular aneurysm which might have as severe dys function and as great a total extent of infarction (Fig 3) Although the clinical presentation of these two entities left ventricular aneurysm and ischemic cardiomyopathy may be indistinguish able their morphologic characteristics and likely their potential for surgical remedy are markedly different With improved noninvasive techniques which provide information on over all shape such as the two dimensional echocardiogram and the thallium 201 myocardial perfusion scan ' the two entities should be identifiable

All 14 hearts were markedly enlarged with an average weight of 625 grams but left ventricular wall thicknesses were disproportionately thin for heart weight even in areas not directly thinned by necrosis or fibrosis The average maximal wall thickness in these hearts was significantly thinner than the values obtained from a group of autop sied patients with recurrent infarctions but with out a myocardiopathy picture ($p < 0 01$) and the walls were thinner than the values obtained for autopsied patients with idiopathic dilated cardio myopathy ($p < 0 001$) and with primary valvular disease ($p < 0 01$)

Congestive heart failure and myocardial infarc tion are a recognized stimulus for myocardial hypertrophy in patients with coronary artery disease The ability of surviving myocardium to hypertrophy in response to injury of part of the left ventricle is a compensatory mechanism how ever only to a point in that it leads to additional tissue requiring additional coronary flow Rack ley and co workers have shown that the degree of left ventricular hypertrophy relative to left ven tricular end diastolic volume was a prognostic indication of post catheterization survival rates with greater hypertrophy for a given end diastolic cavity enlargement carrying a better outlook It has also been shown in patients with primary myocardial disease that the ability of the heart to compensate for its dilatation by developing wall hypertrophy correlated positively with sur vival ' The patients with ischemic cardiomyopa thy studied at autopsy appear to fall into that poorer prognostic group in which the heart is dilated but it not able to appropriately thicken adjacent non infarcted wall Although in primary cardiomyopathy one might suspect that the ina bility of some patients to develop compe

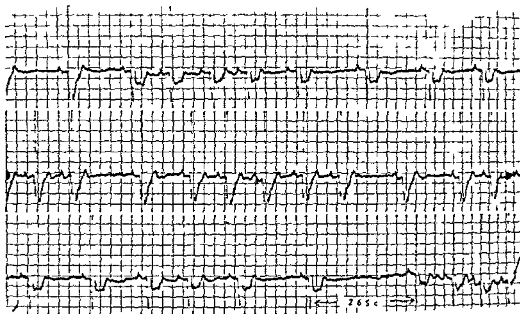

Fig 1 The electrocardiogram indicates frequent sinus pauses (the longest being 2 6 seconds)

at the nose or mouth with a CO_2 analyzer Thoracic breathing movements were determined by measuring transpulmonary pressure changes with an intraesophageal balloon Upper airway obstruction was defined as a cessation of airflow at the nose and mouth in the presence of continued thoracic breathing movements All investigational procedures were carried out with the subject s informed consent under protocols approved by the local Human Experimentation Committee The pre tracheostomy study revealed 312 upper airway obstructions with a mean duration of 16 seconds with a range of 10 to 27 seconds Obstructions were accompanied by prolonged asystole (up to seven seconds) with second degree AV block and marked sinus arrhythmias (Fig 2) O saturations during sleep ranged from 82% to 93% The post tracheostomy study revealed no upper airway obstructive episodes and no clinically significant central apneas or other respiratory abnormalities. There were no significant cardiac arrhythmias The ear oximeter revealed no oxygen desaturations during the study

Electrophysiologic studies From a right femoral vein puncture a tripolar catheter was positioned on the septal leaflet of the tricuspid valve and resting A H and H V intervals were recorded The A H interval representing AV nodal conduction was 140 msec and the H V interval representing His-Purkinje conduction was normal at 50 msec This catheter was switched for a hexapolar catheter which was positioned in the high right atrium in order to study the response of the sinus node to overdrive pacing The patient had a maximum sinus recovery time of 910 msec and a correct sinus recovery time of 260 msec, which indicated normal sinus node function She had normal atrioventricular conduction during rapid atrial pacing

Discussion

There is little information on arrhythmias in the sleep apnea syndrome Kryger and associates[4] reported a case of an obese man who had somnolence and upper airway obstruction His apnea episodes were usually associated with bradyarrhythmias He had atrial fibrillation and flutter with a high degree AV block and asystole lasting up to ten seconds The arrhythmias were abolished by atropine but electrophysiologic studies were not performed Tilkian and colleagues[5] studied cardiac arrhythmias during wakefulness and sleep in 15 patients with sleep induced obstructive apnea Sleep was characterized by marked sinus arrhythmia in 14 by extreme sinus bradycardia in six by asystole or 2.5 to 6 3 seconds in five by complex PVC s in ten and by ventricular tachycardia in two Atropine was partially effective and tracheostomy highly effective in preventing the majority of these arrhythmias during sleep Tilkian and co workers[5] also postulated that these arrhythmias are not due to fixed or anatomic disease of the sinoatrial or AV nodes but that they reflect functional and reversible abnormalities precipitated by sleep-related abnormal CNS functioning They suggested that airway obstruction caused hypoxia which stimulated vigorous inspiratory effort against the closed airway This inspiratory effort activated vagal parasympathetic impulses causing sinus bradycardia Hypoxia and acidosis may also increase sympathetic tone, causing sinus tachycardia PVC s and ventricular tachycardia

Table 1 illustrates the data in our patients

Case reports

Arrhythmias in sleep apnea

Tsutomu Imaizumi M D
Oklahoma City Okla

The original description of the Pickwickian syndrome included obesity periodic breathing with hypoventilation somnolence and cor pulmonale[1] It is now well established that the essential features of this syndrome—i e somnolence hypoventilation and cor pulmonale—can occur in the absence of obesity and with normal carbon dioxide responsiveness[2] This syndrome has been recently called the sleep apnea hypersomnolence syndrome (SAHS) because of the occurrence of obstructive apnea in these patients during sleep Disturbances in cardiac rhythm can occur during sleep[3,4] and multiple arrhythmias have been described in association with the SAHS In this report I describe detailed sleep studies electrophysiologic studies and the clinical data of a patient with the SAHS and briefly present arrhythmias of other patients with this syndrome

Case report

History A 23 year-old black female was admitted to the University Hospital on December 9 1976 because of "sleep trouble" She complained of falling easily to sleep even when she was teaching at a kindergarden Her mother noticed that she fell asleep very easily when she was working She had frequent morning headache Her mother also confirmed that th patient snored noisily and had frequent periods of apnea A hospital record indicated that she had been obese for many years prior to that time She had adenocarcinoma of the endometrium with polycystic ovarian disease and underwent a total vaginal hysterectomy with bilateral salpingo ophorectomies in 1974 Physical examination on admission revealed a very obese black female who appeared older than her stated age and weighed 174 kg The blood pressure was 130/90 mm Hg pulse was 9? per/minute and respiratory rate was ?2 per/minute The skin was dry The head eyes ears nose and throat were unremarkable There was thyromegaly but no palpable nodes The carotid pulses were 2+ bilaterally The chest was symmetrical with equal bilateral expansion The breasts were huge and pendulous without palpable masses The lungs were clear to auscultation and percussion The heart was regular in rhythm without murmurs or gallops The abdomen was massive with fat pads The extremities were obese without edema Neurological examination was within normal limits She had a normal CBC with differentiation SMA18 T3 and T4 Arterial blood gases revealed pH 7 47 PCO_2 37 mm Hg PO_2 72 mm Hg and HCO_3 2? mEq/L Electrocardiograms were all within normal limits with sinus rhythm A chest x ray was free of active infiltrates and the heart size was normal Pulmonary function studies revealed a reduced total lung capacity functional residual capacity residual volume and expiratory residual volume all compatible with mild restrictive disease The diffusing capacity and airway resistance were within normal limits

A sleep study was performed She experienced over 300 episodes of upper airway obstruction with some lasting over 30 seconds These were accompanied by severe cardiac arrhythmias The details will be described subsequently Tracheostomy was performed because of disabling somnolence and severe cardiac arrhythmias She was discharged without medications She had lost some weight and did well with marked reduction in daytime somnolence and headache Hypersomnolence was quickly resolved and the post tracheostomy sleep study revealed no cardiac arrhythmias

Approximately one week prior to her second admission on April 15 1977 she developed constant throbbing headaches with blurred vision She came to the emergency room where her pulse was noted to be slow An electrocardiogram showed frequent sinus pauses (Fig 1) She was admitted to the Intensive Care Unit Physical examination showed that she was somewhat confused Blood pressure was 112/70 mm Hg and her pulse was irregular She weighed 163 kg at this time Other physical findings were unchanged from those of the previous admission Arterial blood gases revealed pH 7 49 PCO_2 8 mm Hg PO_2 ?1 mm Hg and HCO_3 20.5 mEq/L The ECG monitor showed frequent episodes of sinus bradycardia sinus pauses and second-degree heart block not associated with respiration or hypoxia One milligram of atropine was given without effect

Sleep studies In order to determine the presence and extent of upper airway obstruction during sleep the patient was studied in the Sleep Physiology Laboratory Recordings included continuous monitoring of the ECG EEG EOG and EMG for determination of sleep stages The presence of airflow was assessed by recording fluctuations of expired CO_2

not have clinical evidence of organic heart disease, sinoatrial or AV nodal disease is not likely I can hypothesize that increased parasympathetic impulses because of vigorous inspiratory effort against the closed airway caused sinus bradycardia prolonged sinus pause and AV block After abrupt cession of the airway obstruction the parasympathetic tone decreased and there would have been overshoots of sympathetic impulses which could have caused frequent premature ventricular contractions and ventricular tachycardia

Conclusion

Severe cardiac arrhythmias can be seen in patients with sleep apnea These are not likely to be caused by the organic sinoatrial or AV node disease but are due to functional and reversible abnormalities precipitated by the sleep dependent CNS dysfunction Tracheostomy may be effective in controlling the arrhythmias in some patients with obstructive sleep apnea

Summary

A 23 year old black female was referred to the University Hospital of Oklahoma because of sleep trouble She complained of falling asleep easily during the daytime A sleep study was performed which showed prolonged apnea up to 35 seconds and prolonged asystole up to seven seconds with second degree heart block A tracheostomy was performed She had lost so[me] weight and did well until six months later wh[en] she developed severe throbbing headache w[ith] visual blurring She came to the emergency ro[om] and an ECG showed sinus bradycardia w[ith] prolonged sinus pauses up to 2 6 seconds, a[nd] first and second degree AV block She had [no] hypoxia and atropine was ineffective Electrophy[-] siologic studies were performed Details of t[he] case are described and mechanisms of t[he] arrhythmias are discussed

I am grateful to Drs William Orr and Eliot Schec[hter for] reviewing the manuscript

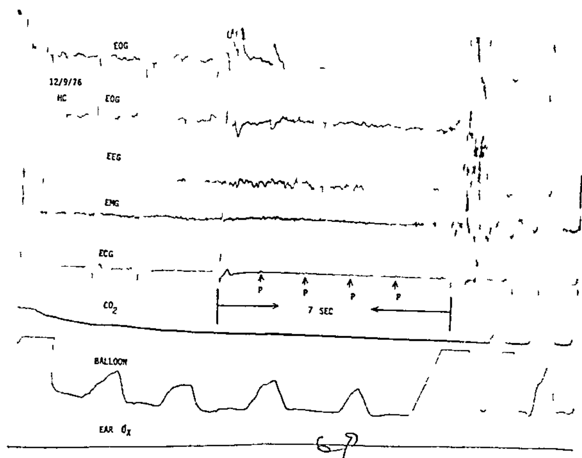

Fig 2 Polygraphic sleep study The flat line of CO indicated prolonged apnea in the presence of breathing efforts shown by fluctuations in the line of the balloon There were 7 seconds of asystole associated with apnea As soon as the patient started breathing normal sinus rhythm was restored *EOG = electrooculogram EEG* = electroencephalogram *EMG* = electromyogram *CO* = CO analyzer *BALLOON* = intraesophageal balloon *P* = P wave

They are all obese (except patient C U) and young (except patient C T) and none had a history suggesting ischemic heart disease and none were on cardiac medication except patient T R Waking ECG s were not impressive During sleep they all had significant cardiac arrhythmias Sinus arrhythmia (not listed here) occurred in all patients in association with episodes of upper airway obstruction Patients C V and T R had no arrhythmias after a tracheostomy

Only patient H C (the subject of this case report) had electrophysiologic studies She had prolonged asystole (seven seconds) with second degree AV block before tracheostomy Arrhythmias persisted after tracheostomy however they were much milder We gave atropine intravenously which was not effective and arrhythmias were not associated with hypoxemia This suggests another mechanism of arrhythmia in the patient

Since electrophysiologic studies were normal during wakefulness sinoatrial or AV nodal disease is not likely Then what are the mechanisms of arrhythmia in the patient? As shown in Fig 2 she had airway obstruction with inspiratory effort evidenced by the flat CO line and the cyclic shift of the line of balloon During this airway obstruction the parasympathetic nerve must have been activated which could have caused second degree heart block with prolonged asystole It is interesting to note that she was well for six months after a tracheostomy and when she developed arrhythmias she had severe headache and she was somewhat confused Thus we can hypothesize that an acute central nervous event may have caused these arrhythmias although she had no other evidence of CNS dysfunction

How about the mechanism of the other patients? Since most of them are young and did

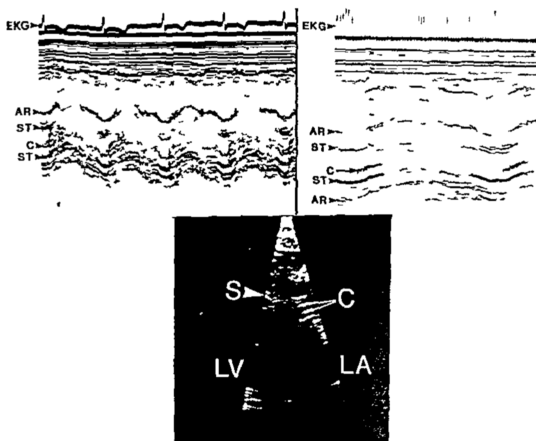

Fig 1 M mode and two dimensional echocardiogram of the stenotic porcine aortic valve are shown. *Left upper panel* increased cu p echoes with restricted cusp motion during systole are depicted *Right upper panel* after reducing the coarse gain the high frequency low amplitude fluttering of the thickened cu ps (C) are visualized. *Lower panel* a systolic frame of the two dimensional echocardiogram is shown Note the marked reduction (< 10 mm.) of the cusp opening AR = aortic root C = cusps EKG = electrocardiogram LA = left atrium LV = left ventricle S = ventricular septum ST = porcine valve stents

phy but was clearly reduced on the two dimensional study This is comparable to the previous reports in which the two dimensional echocardiography because of its greater spatial orientation was found to be more useful than the M mode study in assessing the valve opening and stenosis of the native aortic valve The systolic opening of the porcine cusp however as with the native aortic valve may be influenced by left ventricular stroke volume The left ventricular function and stroke volume were normal in our patient and would not account for the reduced cusp opening of the porcine valve

The significance of the systolic fluttering noted on the M mode study of our patient cannot be determined Similar flutter has been reported in a normal native aortic valve but has not been observed in a normally functioning porcine aortic valve[5] It is possible that the systolic flutter may be a normal finding which has not yet been reported in the relatively small number of echocardiographic reports dealing with the functio[n]ly normal porcine bioprosthesis in the ao[rtic] position Another possible explanation of systolic flutter may be as a result of turbulen[t] blood flow across the stenotic and thicke[ned] porcine cusps Further studies are needed in [this] area before firm conclusions can be drawn

The etiology of porcine valve stenosis is [not] exactly clear Most likely it is a result o[f a] degenerative process similar to that previou[sly] reported by light and electron microscopic st[udies] of these valves[6]

In conclusion both modes of echocardiograp[hy] are of value in evaluating stenosis of the porc[ine] aortic valve a condition which may be amen[able] to valve replacement surgery

Summary

M mode and two-dimensional echocard[io]graphic features are reported in a patient [who] developed severe stenosis of a porcine xenogr[aft]

Echocardiographic features of a stenotic porcine aortic valve

Mohsin Alam M D
Sidney Goldstein M D
Detroit Mich.

The echocardiographic features of porcine valve degeneration have recently been reported These reports have confined their descriptions to aortic insufficiency, mitral stenosis and insufficiency occurring in the degenerating porcine xenograph Although stenosis of the porcine valve in the aortic position has been noted to occur the echocardiographic features were not described due to the inability to visualize the valve adequately Subsequent to our initial reports we have observed an additional patient with stenotic degeneration of the porcine xenograph in the aortic position that occurred 60 months after implantation

Case history

D D a [illegible]9-year-old male underwent an aortic valve replacement with a porcine xenograph (Hancock) valve Six years later he was seen again complaining of pressure like chest pain and dyspnea on minimal exertion He also complained of frequent light headed spells, without syncope There was no history of paroxysmal nocturnal dyspnea, fever or chills

Physical examination revealed a blood pressure of 120/80 mm Hg pulse 80/minute and regular The carotid pulse upstroke was prolonged and a systolic thrill was palpable in the second right intercostal space The aortic component of the second heart sound was diminished A grade IV/VI systolic ejection murmur radiating to the carotid vessels and grade II/VI diastolic blowing murmur were present at the second right intercostal space and the lower left sternal border The diastolic murmur had not been present on a physical examination performed a year previously and the intensity of the systolic murmur had increased.

Pertinent laboratory studies including hemoglobin platelet total and differential white blood count and blood cultures were all within normal limits The electrocardiogram revealed left ventricular hypertrophy with strain pattern Chest x ray revealed left ventricular enlargement and on fluoroscopy porcine valve calcification was noted Cardiac catheterization revealed a peak porcine aortic valve gradient of 88 mm Hg with calculated valve area of 0 [illegible]3 square centimeters. Angiography revealed moderate porcine aortic valve insufficiency with normal coronary arteries.

An M mode and a two-dimensional echocardiogram using conventional techniques and instrumentation (Smith Kline Ekoline 20-A and Ekosector I) were performed within one week of cardiac catheterization and porcine valve replacement surgery Both modes of echocardiography revealed an increase in porcine cusp echoes (Fig 1) The M mode study in addition revealed high frequency low amplitude systolic fluttering of the cusps The opening of the valve could not be accurately measured on the M mode study due to increased echoes from the thickened cusps. The systolic opening of the porcine cusps however was clearly visualized and was markedly reduced on the two-dimensional study (Fig. 1)

The gross examination of the porcine valve at the time of surgery revealed thickened and stenotic cusps with multiple calcific nodules and scarred retraction of the cusp margins (Fig 2)

Discussion

M mode echocardiography has been reported to be useful in evaluating a stenotic mitral porcine valve[1] Although severe stenosis of a porcine valve has also been reported in the aortic position[1] the echocardiographic features of this entity have not been reported The increased cusp echoes in our patient were associated with thickening and calcification of the valve cusps which was demonstrated at the time of surgery Echocardiographic features of the stenotic porcine valve in the mitral position have shown a similar increase in cusp echoes with identical gross anatomic findings.[3] As a result of increased cusp echoes, the porcine valve opening could not be clearly demonstrated by M mode echocardiogra

Case report

A 72 year-old man was hospitalized for massive edema of the legs, increase in abdominal girth of recent onset weakness and anorexia He had previously been healthy and he specifically denied antecedent hypertension or heart disease A diagnosis of congestive heart failure was made on the basis of findings of cardiomegaly pitting dependent edema ascites hepatomegaly and bilateral basal pulmonary rales

Pertient laboratory data were as follows hemoglobin 18 4 Gm /dl. hematocrit 63% RBC 6 73 million/cu mm WBC 13 100/cu mm with 48% mature neutrophils 6% bands 18% lymphocytes 2% eosinophils and 1% basophils platelets 30 000/cu mm Leukocyte alkaline phosphatase score was 162 (control 76) Total blood volume was 19,500 ml (predicted value 5 700 ml.) the red cell mass was 9 000 ml (predicted value 2 500 ml) The results of serum chemical analysis were as follows LDH 790 MU /ml (laboratory normal 90 to 200 MU /ml) SGOT 90 MU /ml (laboratory normal 10 to 50 MU /ml) total bilirubin 3.8 mg /dl total protein 5 8 Gm / dl albumin 2 94 Gm /dl uric acid 9 5 mg /dl. BUN 19 mg./dl calcium 8 1 mg./dl and alkaline phosphatase 90 MU /ml (laboratory normal 30 to 85 MU /ml.) The serum electrolyte values were within normal limits except for a slightly elevated value for serum sodium of 148 mEq /L. Chest roentgenogram demonstrated an enlarged heart [illegible] pleural effusion Gastrointestinal series and intraveno[us] ogram studies were normal except for displacement [illegible] ach and left kidney by an enlarged spleen Liver sc[an] Au [illegible] showed hepatomegaly without focal intra[hepatic] lesions The ECG showed ST T wave abnormalities [illegible] marrow aspiration was dry but a biopsy showed prom[inent] erythroid hyperplasia megakaryocytosis, eosinophil[ia] fibrosis

With the clinical diagnosis of congestive heart [failure] secondary to arteriosclerotic coronary artery diseas[e] patient was treated with digitalis diuretics and phlebot[omies] Lowering of hematocrit to below 50% was achieved by pe[riodic] phlebotomies However the congestive failure proved intractable and he died 6 months later of refractory cong[estive] failure with left pleural effusion massive ascites, and an[asar]ca

Pathology

At autopsy the heart was hypertrophied and weighed [illegible] grams the maximum thickness of the right and the [left] ventricular wall being 0 3 and 1.8 cm respectively A mas[sive] intramural thrombus covering the endocardial surface of [the] left ventricle in its entirety was observed The thro[mbus] extended from the apex of the heart and reduced the capa[city] of the left ventricle by about 70% (Fig. 1) Microscopica[lly the] thrombus displayed various stages of organization the su[rface] exposed to the blood flow was well endothelialized 45 [illegible] major branches of both the right and left coronary arte[ries] showed minimal arteriosclerotic changes No significant n[ar]rowing of the arterial lumina was demonstrable The myoca[r]dium beneath the intramural thrombus was studied by mu[lti]ple sections No evidence of any recent or remote infarct wa[s] observed

In the gross examination of the various viscera, seve[re] passive venous congestion was observed especially in the lungs and the liver The liver weighed 2,400 grams and cr[oss] section showed a nutmeg appearance The large pu[lmonary] arteries showed prominent arteriosclerotic plaques The spleen was massively enlarged weighed 1,200 grams and se[v]eral sections, displayed many areas of infarction His[tologi]cally pronounced extramedullary hematopoiesis and [illegible]

Summary

The occurrence of thrombotic events is central to the course of polycythemia vera[1] Myocardial cerebral peripheral and pulmonary infarctions are frequent and are consequences of thromboses in small and medium caliber arteries Thrombosis in large caliber arteries is a rare event Thrombosis within the chambers of the heart has not been hitherto reported

This report documents the occurrence of massive left ventricular thrombosis in a patient with polycythemia vera The thrombus reduced the left ventricular capacity by about 75% and caused intractable congestive heart failure

The help of Gertrude Martin is gratefully acknowledged in preparation of the manuscript

Discussion

Cardiac function and cardiac output are usual ly normal in polycythemia vera [6] The clinical course of the patient reported in this paper was highly unusual while the diagnosis of polycy themia vera was readily made by the hematologic udies and blood volume determinations the ue nature of its relationship with congestive eart failure remained masked The probability of e cardiac failure being secondary to arterioscle otic coronary artery disease or the existing ematologic disorder was clinically suspected hough the electrocardiographic evidence for this as lacking At autopsy the clinical picture of efractory heart failure was related to the pres nce of the left ventricular thrombus per se eference to the literature on intracardiac umors and thrombi shows that tumors in the ight heart are associated with weakness edema epatomegaly and ascites Space occupying esions in the left heart are associated with dysp ea orthopnea and with emboli to the central ervous system renal mesenteric and peripheral rteries In view of the closer correspondence of his patient s clinical manifestations to those of patients with compromised right ventricular function we offer the hypothesis that this patient s thrombus either interfered with mitral valve function or so gradually but progressively interfered with left ventricular filling that the process became a physiological equivalent of mitral stenosis with the subsequent development of pulmonary hypertension and right ventricular failure From a functional standpoint the patho genetic mechanism for the intractable heart fail ure seen in this patient is closely analogous to the hemodynamic impairment observed in patients with endomyocardial fibrosis [7] In this entity found primarily among Africans the fibrotic pro cess with or without thrombus formation may so seriously reduce the ventricular capacity as to prove fatal

Rheologic factors are known to play an impor tant role in the local propagation of clotting It is likely that this clot formed slowly by accretion on a small starting nidus The large size of the clot the many stages of organization seen in the thrombus the completely endothelialized sur face the absence of an acute arterial occlusive event and the prolonged (6 month) course of this patient are all consistent with this hypothesis The nature of the event initiating the intraven tricular clotting was obscured by the reparative processes within the clot

Had echocardiographic studies been performed the clot might have been detected [8] Its removal might have restored the left ventricular capacity and relieved intractable congestive failure

Summary

The occurrence of thrombotic events is central to the course of polycythemia vera[1] Myocardial cerebral peripheral and pulmonary infarctions are frequent and are consequences of thromboses in small and medium caliber arteries Thrombosis in large caliber arteries is a rare event Thrombosis within the chambers of the heart has not been hitherto reported

This report documents the occurrence of massive left ventricular thrombosis in a patient with polycythemia vera The thrombus reduced the left ventricular capacity by about 75% and caused intractable congestive heart failure

Echocardiographic diagnosis of left ventricular thrombi

Patricia C Come M D
John E Markis M D
Hugh S Vine M D
Barry Sacks M D
Colin McArdle M D
Alberto Ramirez M D
Boston Mass

Although left ventricular thrombi are frequently found at postmortem examination and can be identified angiographically[3] in many patients with cardiovascular disease they have only recently been identified by echocardiographic techniques [9] Reports of their recognition are still few and the M mode and cross sectional echocardiographic appearances of the clots have been variable Presented below are two patients with left ventricular thrombi recognized echocardiographically and documented by pathologic and/or angiographic examination whose M mode and cross sectional echocardiograms add to the spectrum of echocardiographically detectable ventricular clot The sensitivity and specificity of echocardiographic techniques in the diagnosis of intracardiac thrombi are discussed

Methods

The M mode and cross sectional echocardiographic studies in each patient were performed with the patient s chest elevated 15 degrees and with the patient turned 30 degrees into a left lateral position

M mode echocardiograms were obtained using an Irex 101 or System II Ultrasonoscope coupled with a 2 25 MHz transducer focused at 7 5 cm They were recorded on an Irex System II recorder The echocardiographic transducer was placed along the left sternal border in the third or fourth intercostal space and was angled inferiorly and laterally to record echoes from the left ventricle An attempt was made to scan toward the apex

Cross sectional echocardiographic scans were obtained in multiple planes using the 80 degree Varian Model 3000 Phased Array Sector Scanner A long axis view of the heart approximating a sagittal plane was obtained by positioning the transducer in the third or fourth intercostal space to the left of the sternum and directing the plane of the sweep from the inferior wall of the left ventricle to the base of the heart An attempt was made in each patient to visualize the apex in the sagittal plane by placing the transducer at the position of the apical impulse and directing the plane of the sweep superiorly and inferiorly Such a change in transducer position is necessary for visualization of the left ventricular apex in the sagittal plane since in most patients an echocardiographic scan from the apex to the base of the heart involves changing the plane of the echocardiographic sweep Short axis (transverse) views of the left ventricle were obtained by positioning the transducer along the left sternal border or at the apex (for a transverse view of the apex) and directing the plane of the sweep perpendicularly to the long axis of the heart along an imaginary line connecting the left shoulder and the right hip Four chambered views from the apex were

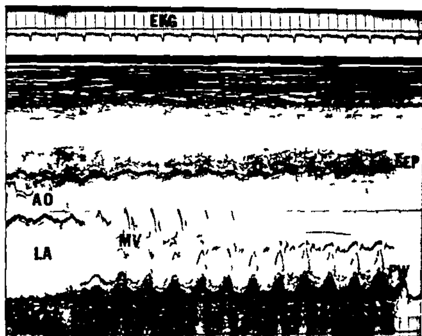

Fig 3 M mode echocardiographic scan from the aortic root (*AO*) and left atrium (*LA*) to the left ventricle in Patient No 1 after removal of 78 grams of left ventricular thrombus The left ventricle remains enlarged. The septum (*SEP*) is dyskinetic *MV* = mitral valve *PW* = posterior left ventricular wall *EKG* = electrocardiogram

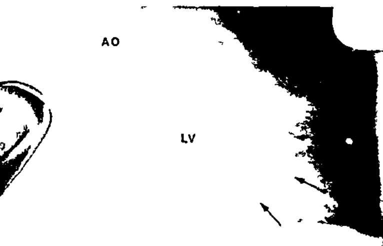

Fig 4 Left ventriculogram in the right anterior oblique projection in Patient No 2 Angiographic dye fails to fill the entire left ventricle due to the presence of a large apical mural thrombus which appears to be adherent to the left ventricular wall *Arrows* demonstrate the border between dye and mural thrombus *AO* = aortic root *LV* = left ventricular cavity

wall moved well and because the thrombus appeared to be confined to the apex on cineangiographic study It is perhaps more likely that the band of echoes represented an echo producing pericardial effusion with adhesions between epicardium and pericardium resulting in movement of the pericardium If so failure to identify thrombus by M mode echocardiographic tech nique may have been due to the inability to sca down into the apical region On cross sectiona echocardiographic examination a well-define echocardiographic density was observed adjacen to and moving with the ventricular apex N pericardial effusion was apparent Angiograph findings were diagnostic of a left ventricula thrombus which appeared firmly adherent to th apical wall

Although left atrial and left ventricular throm bi are found far more frequently at postmortem examination than are primary or secondary intra cardiac tumors[1] [11,13] reports of their recogni tion by echocardiographic techniques have bee relatively few[9,11,13] compared to multiple reports of echo diagnosis of intracardiac neoplasms[1,3] In a study by Ports and associates' of e patients with surgically proven left ventricul thrombi none were detected by M mode echoca diography and only the four largest thrombi we detected by cross sectional techniques. In anoth er study by DeMaria and co workers cross sectional echocardiography detected den ties compatible with apical thrombus in five patien who experienced peripheral emboli follow myocardial infarction The M mode echocard grams in those patients revealed no signs of thrombi The ability of echocardiographic tech

areas of firm white tissue thought to represent focal organization The right and left brachial artery emboli were identified as recent thrombus.

Postoperative M mode echocardiography (Fig 3) revealed *disappearance of the previously noted intraventricular echoes.* The patient made a satisfactory recovery and was discharged on the sixteenth postoperative day on digoxin and sodium warfarin Ventricular ectopy was markedly diminished on no medications. Following discharge however progressive severe congestive heart failure developed and the patient died seven months after surgery

Case report No 2

P D a 3? year old man with a history of anterolateral transmural myocardial infarction four months previously was admitted to Beth Israel Hospital for cardiac catheterization to evaluate post myocardial infarction angina pectoris. Medications included propranolol and nitrates.

On physical examination the pulse was 80 and regular the blood pressure was 130/80 mm Hg and the weight was 238 pounds There was no evidence of jugular venous distension rales, murmurs or gallops The electrocardiogram revealed changes of an old anterolateral myocardial infarction The chest x ray was normal, without cardiomegaly or evidence of failure Cardiac catheterization revealed an elevated left ventricular filling pressure of 17 mm Hg a cardiac index of 2 6 liters per minute and an ejection fraction of 44% The left ventricle was dilated and there was paradoxical motion of the anterior wall and apex A large apical left ventricular filling defect was present and appeared to be adherent to the left ventricular myocardium (Fig 4) The right coronary artery was occluded proximal to the crux. The left coronary artery had diffuse irregularities but no apparent critical stenosis. Surgery was not recommended

M mode and cross sectional echocardiography were performed following cardiac catheterization. The M mode echocardiogram (Fig 5) revealed a markedly dilated left ventricle measuring 8.2 cm in diameter The septum which measured 11 mm in thickness in end-diastole moved paradoxically and failed to *thicken with systole The posterior wall demon*strated normal systolic motion but there were multiple echoes from the posterior wall of the heart measuring 22 mm in end-diastole The cross sectional long axis and four-chambered apical views (Fig 6) demonstrated an intraventricular mass adherent to the left ventricular apex The mass was well defined and both it and the underlying myocardium moved dyskinetically There was no apparent pericardial effusion on the cross-sectional views

Discussion

The echocardiographic appearances of intracardiac thrombi are variable [11 3] Left atrial thrombi have been recognized by abnormal linear densities or by masses of echoes within the left atrium [8 11 3] The appearances of left ventricular thrombi have ranged from fine dust like densities [3] to more discrete clusters or bands of echoes adherent to the septum or occupying the apical region of the left ventricular cavity [6] The echocardiographic findings in our two patients add to the reported spectrum of appearance of intracardiac thrombi In the first patient a dense mobile mass of echoes was seen to partially fill the left ventricular cavity and appeared during systole to move into the left ventricular outflow tract There was no apparent connection of this mass to the left ventricular wall on either M mode or cross sectional echocardiographic examination The movement pattern of the mass seen well on the cross sectional study would make differentiation from a mobile intraventricular neoplasm such as a ventricular myxoma impossible In the second patient it is unlikely that the M mode echocardiographic appearance of abnormal thickness of the posterior wall represented thrombus adjacent to myocardium because the posterior

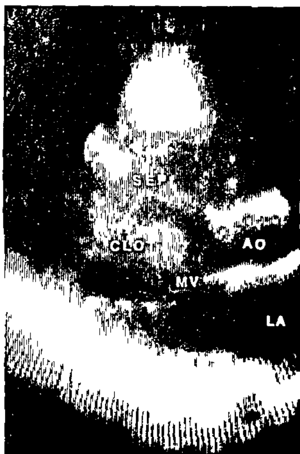

Fig 2 Preoperative cross sectional recording of the heart in Patient No 1 A dense mass of echoes representing the surgically confirmed clot, is seen to fill much of the left ventricular cavity during diastole The mass appeared freely mobile and without obvious attachment to the septum (*SEP*) or mitral valve leaflets (*MV*) During systole the echogenic mass was seen to move further into the left ventricular outflow tract *AO* = aortic root *LA* = left atrium

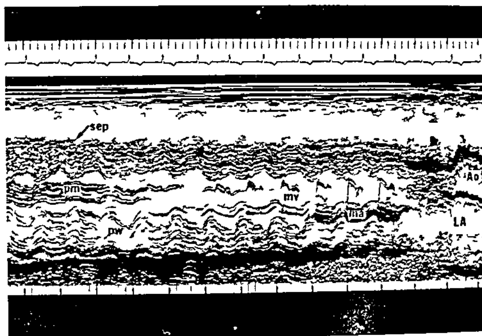

Fig 7 Slow scan from the apex of the left ventricle to the aortic root (*AO*) and left atrium (*LA*) in a hypertensive patient with severe concentric hypertrophy of the septum (*SEP*) and posterior wall (*PW*) A thick dense band of echoes representing a hypertrophied papillary muscle (*PM*) is seen within the left ventricular cavity *MV* = mitral valve *MA* = mitral annulus

metastatic neoplasms may produce echocardiographic patterns similar to thrombus Normal intracardiac structures which have become thickened or calcified may cause abnormal echoes within the left ventricular cavity Due to failure of lateral resolution a calcified mitral valve annulus may on M mode or cross sectional echocardiographic study appear to extend inferiorly into the left ventricular cavity[3] Calcified chordae or papillary muscles[1] may give the appearance of a dense intraventricular mass In such cases cross sectional echocardiography may help to clarify the origin of abnormal echoes seen on M mode study because it allows better recognition of anatomic relationships and movement of structures relative to one another This is illustrated by the recent study in our laboratory of a 32 year old woman with a long history of hypertension and left ventricular hypertrophy Severe concentric left ventricular hypertrophy was noted on the echocardiographic studies with septum and posterior wall both measuring 23 mm The mitral annulus appeared calcified With scanning inferolaterally toward the left ventricular apex on M mode echocardiography (Fig 7) a dense mass of echoes similar to that seen in patient No 1 was observed to partially fill the left ventricular cavity On one dimensional examination those echoes appeared to be separate from septum and posterior wall However the two dimensional echocardiogram revealed that the abnormal mass of echoes represented papillary muscle continuous inferiorly with the apical ventricular wall and superiorly with chordae giving support to the mitral valve leaflets (Fig 8)

The cases presented serve to further illustrate the variable echocardiographic appearances of left ventricular thrombi and emphasize the potential difficulties of differentiating them from other intracardiac structures or mass lesions Strict attention to echocardiographic technique may improve the sensitivity of echocardiography in the detection of left ventricular thrombus Since thrombus is located most commonly in the left ventricular apex[3] an attempt must be made to scan inferiorly and laterally toward the apical region on M mode examination A slow sweep from the apex to the base of the heart may allow recognition of focal wall thickening which may be produced by overlying mural thrombus The use of multiple cross sectional views such as the long and short axis views with the transducer placed at the apex and the four chambered apical view[1] should allow optimal study of the apex and improve the sensitivity of cross sectional echocardiography in the detection of thrombi

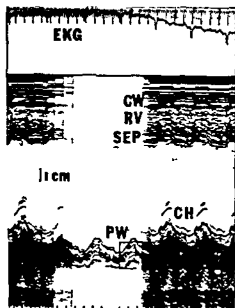

Fig 5 M mode echocardiographic recording from Patient No 2 shows a dilated left ventricle The septum (SEP) move paradoxically and fails to thicken during systole compatible with prior infarction Multiple echoes (PW) measuring 22 mm in width at the end of diastole are recorded from the region of the posterior wall and pericardium EKG = electrocardiogram CW = chest wall RV = right ventricle CH = chordae 1 cm = one centimeter

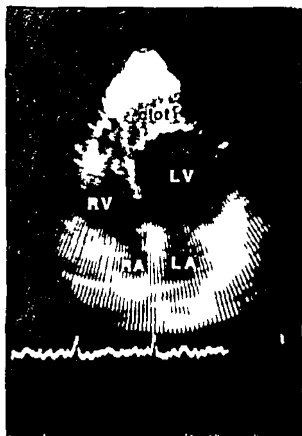

Fig 6 Cross sectional echocardiographic recording of the four-chambered apical view in Patient No 2 shows a large echogenic mass adherent to the ventricular wall and filling the apex (clot) LV = left ventricle LA = left atrium RV = right ventricle RA = right atrium. The electrocardiogram is below the echo

niques to identify thrombi is probably limited by several factors First the thrombus may be too small to be recognized Secondly the echocardiogram will be unable to record echoes from a thrombus if the sound beam is not directed toward the mass Since many left atrial thrombi are located within the atrial appendage a part of the heart not visualized by routine echocardiographic scanning recognition of those intra atrial thrombi by usual echocardiographic techniques is not possible Most left ventricular thrombi are located in the apex of the left ventricle[3] and will not be visualized unless the beam can be directed toward the apex The apparent increased sensitivity of cross sectional echocardiography over M mode echocardiography in the recognition of left ventricular masses[5] is probably in part due to the ability of cross sectional techniques to visualize many more regions of the heart particularly if multiple echocardiographic planes are examined Finally the difference in acoustic impedance of blood and thrombus or of ventricular wall and thrombus may be insufficient for adequate reflection of sound waves at their interfaces Ports and colleagues[3] noted that those thrombi recognized echocardiographically had layers of organized thrombus alternating with areas of more recent thrombus formation In the first patient presented above the thrombus seen readily by echo techniques as a dense mass of echoes also contained areas of fresh thrombus as well as areas of organized thrombus If such inhomogeneity is associated with differences in acoustic impedance such layered thrombi may produce sufficient reflection of ultrasound to allow their recognition This is likely since it is known that the reflection characteristics of body tissues are in large part dependent on their content of collagenous fibers

Unfortunately echocardiographic patterns suggestive of thrombus may not be specific Variations in gain and reject settings and reverberations may produce spurious echoes within an intracardiac chamber Intracardiac primary and

Since the echocardiographic patterns are not specific for thrombus however other possibilities must be considered when an abnormal mass of echoes is demonstrated Those would include artifacts primary or metastatic tumors and normal intracardiac structures which have become more intensely echo producing due to alterations in their size anatomic position within the heart or acoustic impedance properties

Summary

Left ventricular thrombi have not been commonly recognized by M mode or by cross sectional echocardiographic techniques despite their frequency at postmortem examination in patients dying of cardiovascular disease We discuss two patients with left ventricular thrombi recognized echocardiographically and confirmed by pathologic and/or angiographic evaluation whose M mode and cross sectional echocardiographic abnormalities add to the variable spectrum of appearance of left ventricular thrombi The sensitivity and specificity of echocardiographic techniques in the diagnosis of intracardiac thrombi are discussed

Fig 8 Cross-sectional long axis, diastolic view of the heart in the patient with left ventricular hypertrophy demonstrates the severe thickening of the septum (*VS*) posterior wall (*PW*) and papillary muscle (*PM*) The *tip of the arrow* points to chordal attachments between the anterior leaflet of the mitral valve and the papillary muscle A calcified mitral annulus is seen below the *base of the arrow* *AO* = aortic root *LA* = left atrium The electrocardiogram is below the echo

Table I Classification of interventions used to reduce indices of infarct size in patients or infarct size in animals

	Reduction of experimental infarct size	*Effect on indices of infarct size in patients*
1 Relief of vascular obstruction		
Antithrombotic agents	Heparin reduces tissue necrosis	Reduces ST segment elevation[14]
Antiplatelet agents	Aspirin does not alter thrombus	Not tested
Relief of spasm Ca antagonists	Complex action including increased collateral flow specific reduction of contractility in ischemic zone[2] and afterload reduction	Reduction of load on heart and of ST-elevation and reduction of predicted enzymatic infarct size in 9 of 11 patients
2. Increased collateral flow or diffusion to ischemic zone		
Nitrates	Increased collateral blood flow[4] [90]	See Tables V VIII and references 190-195
Hyaluronidase	Reduces QRS changes and necrosis	See Tables V VII and reference 206
Intra aortic counterpulsation	Reduces ischemic injury	Not tested but see reference 236
Surgical reperfusion	Data controversial see reference 2	Not tested
3 Relief of load on heart		
Nitrates (see also Section 2 Table I)	Reduces load[100] ST ↓ [90] [90] CK preservation[90]	ST ↓ with intravenous NG [95] for sublingual NG see references 191 19?
Nitroprusside	Controversial effects	Controversial effects on ST segment, see references 200 and 244
Other vasodilators		
Ca antagonists	Reduction of necrosis	Reduction of predicted infarct size
Diazoxide	No data	Increased ECG changes in 9 of ?0 patients
Ganglion blockade	For general effects of afterload reduction see reference 1	Trimethaphan reduces predicted infarct size
4 Catecholamine antagonists		
β blocking agents	ST ↓ CK preservation lessened necrosis	ST ↓ less CK release improved metabolism see Table II
α blocking agents (phentolamine)	Not documented	Only hemodynamic data[84]
5 Specific metabolic measures		
Increased provision of oxygen	Reduction of infarct size[2]	ST elevation ↓
Inhibition of fatty acid metabolism	Decreased enzyme release	ST elevation ↓
Glucose insulin potassium	Decreased necrosis improved metabolism[60]	Inotropic effect without CK effects[43]
Calcium antagonists	(see Relief of spasm)	(see above)
Prevention of severe cellular acidosis	Not fully tested may be effective	Not tested
Stabilization of membranes	Steroids reduce ischemic injury[58] and infarct size[50] with mummification[30]	Controversial effects reduce Q wave formation
Prevention of cell swelling	Mannitol reduces necrosis only after temporary ischemia[25] but not after prolonged occlusion	Not tested

series of fundamental papers in 1963 showed that pronethalol which lacked intrinsic sympathetic activity could relieve angina pectoris in patients with ischemic heart disease Pronethalol was soon superceded by propranolol which strangely had no apparent effect on angina in its first trial[13] although propranolol is now established as a major advance in the therapy of angina Many of the more recent studies are with the cardiospecific agent practolol which has a certain amount of intrinsic sympathetic activity but now cannot be used for long term therapy because of serious undesirable side effects Of the large number of β blocking agents currently available relatively few have been tested in patients with acute myocardial infarction (Table II) The more recent recognition that similar factors to those precipitating angina can act to increase ischemic damage in developing infarction (see Fig 1 Part 1) made it logical to search for effects of β blockade on infarct size

In view of the established effects of propranolol on heart rate and afterload reduction and the recently reported effects on collateral flow (see

Myocardial infarct size Part 2 Comparison of anti infarct effects of beta blockade glucose insulin-potassium nitrates and hyaluronidase

Lionel H Opie M D
Cape Town South Africa

Based on the principles discussed in the first part of this review the following interventions (Table I) could be expected to limit infarct size (1) relief of vascular obstruction (2) increased collateral flow or diffusion to the ischemic zone (3) relief of the load on the heart thereby promoting a more favorable balance between the oxygen supply and demand (4) catecholamine antagonism and (5) specific metabolic measures Table I lists those agents tested in patients for therapeutic effects on indices of infarct size Because the role and exact nature of the vascular obstruction is so controversial agents acting at that level have been omitted from further consideration and one agent has been selected from each of the remaining categories (2 to 5) of Table I

Thus the four anti infarct agents selected for consideration in further detail are β blockade glucose insulin potassium nitrates and hyaluronidase β blockade is selected because of the exceptionally full experimental and clinical studies now available and because of a combined hemodynamic and metabolic action Glucose insulin potassium is selected as one of the first interventions introduced and now well studied over many years it is an agent likely to counteract undesirable metabolic changes in acute infarction Glucose insulin potassium is compared with the use of a nicotinic acid analog which also has an antilipolytic action Nitrates are selected because of their dual mechanism of action both by causing coronary vasodilation and by reducing the pre and afterload on the heart In addition nitrates as therapeutic agents are well known to all practicing cardiologists Nitroprusside is considered together with the nitrates although nitroprusside has a more definitive effect on the afterload than do nitrates Finally hyaluronidase is chosen as a well investigated agent with minimal side effects and no known hemodynamic mode of action

Other promising agents have been omitted although of great potential interest because of the limited number of patient studies available For example the effects of *steroids* are well documented in experimental preparations Although they diminish the features of acute ischemic injury probably acting by means of membrane stabilization they also inhibit wound healing and hence increase the risk of ventricular rupture or aneurysm (See also Table I references 250 251 256 and 257) Another interesting category of agents the calcium antagonists are only now being studied in patients

1 β blockade

Effects of propranolol on ischemia Black in 1957 searched for a compound to improve ischemia by reducing the effects of sympathetic stimulation and decreasing the myocardial oxygen demand [3] The dichloro analog of isoproterenol was the first compound found to inhibit the adrenergic receptors of the heart but the marked stimulant effect on the heart rate (intrinsic sympathetic activity) obviously limited the therapeutic potential of this type of compound.[3] A

Table III Contraindications to β blockade used in various studies

Parameter	Definition	Author
1 Heart failure	Clinical	
	Cardiomegaly	Mueller et al
	Severe dyspnea	Waagstein and Hjalmarson
	Crepitations 3rd heart sound venous pressure exceeding 3 cm above sternal angle	Barber et al.
	Signs of poor peripheral circulation—eg., coldness or pallor	Waagstein and Hjalmarson
	Cardiac index < 2.5	Gold et al.
	Radiological	Peter et al.
	Interstitial edema or pulmonary edema but pulmonary venous congestion accepted	
2. Hypotension	Systolic cuff pressure	Mueller et al.
	110 mm. Hg	
	< 100 mm. Hg	Waagstein and Hjalmarson
	Mean arterial pressure	
	< 75 mm. Hg	Gold et al.
3 Bradycardia	Rate below 80/min	Gold et al.
	Rate below 65/min	Mueller et al.
	Rate below 60/min	Peter et al.
	Rate below 45/min.	Waagstein and Hjalmarson
4. Conduction defects	No AV block	Mueller et al.
	AV block exceeding first-degree	Peter et al.
	QRS duration not more than 100 msec.	Waagstein and Hjalmarson
5 Lung disease	History of chronic lung disease or asthma for propranolol	Mueller et al.
6. Age	Over 65 excluded for propranolol	Peter et al.

The β blocking agents used are (a) Propranolol, (b) Practolol or metoprolol (c) Practolol.

changes and the metabolic effects of β blockade are of much interest Opie and Thomas found that propranolol pretreatment reduced considerably the uptake of free fatty acid by the ischemic zone of coronary ligated dog hearts while the uptake of glucose was correspondingly increased Their findings are in agreement with the increased respiratory quotient of the heart in patients given propranolol[140] The net metabolic effect was a change from the metabolism of free fatty acids to that of glucose with a decreased oxygen uptake

It is not possible at present to clearly decide whether it is the metabolic or the hemodynamic effects of β blockade which are of greatest importance In patients substantial decreases in precordial ST segment elevation could be obtained by practolol even in those patients in whom the heart rate did not fall But if the metabolic effects on fatty acids were of importance then drugs such as propranolol, oxprenolol and acebutolol which are antilipolytic should be considerably more effective than drugs such as metoprolol which are not antilipolytic[144] Proof of such distinctions is still awaited

In summary most experimental evidence shows that β blockade causes myocardial mechanical metabolic and blood flow effects which are favorable to the outcome of developing myocardial infarction

Propranolol in patients with acute myocardial infarction In patients with acute myocardial infarction (Table II) Gold and associates recently reported that intravenous propranolol given to 12 selected patients caused an abrupt decrease in the ST segment elevation and decreased the incidence of arrhythmias. There were also substantial reductions in the arterial pressure the heart rate and the cardiac output but perhaps surprisingly heart failure did not develop as indicated by the pulmonary capillary wedge pressure which remained unchanged. In another important study, Mueller and co-workers showed that although the myocardial oxygen consumption per beat was decreased by intravenous propranolol and the myocardial blood flow was slightly reduced nevertheless lactate metabolism improved

These effects of propranolol on ischemic myocardium in patients have not yet been matched by studies with measurements of infarct size apart from the study of Peter and colleagues on highly selected patients. That study found decreased release of creatine kinase which was, however evident only

Table II β blocking agents used in patients with the clinical syndrome of acute myocardial infarction recent studies

Authors	*Agent*	*Route and dose*	*When given*	*Result*
Mueller et al	Propranolol	0 1 mg /kg in 3 divided doses at 5 minute intervals	6-8 hours after admission for acute transmural myocardial infarction (including inferior infarction)	Improved myocardial metabolism slight rise (2 mm Hg) in pulmonary wedge pressure
Gold et al.	Propranolol	I V 0 15 mg /kg	Anterior myocardial infarction within 8 hours of onset with persistent pain	Cardiac output fell but pulmonary wedge pressure did not rise ventricular irritability decreased decreased ST-elevation
Peter et al.	Propranolol	I V 0 1 mg /kg over 10 min followed by 320 mg over next 27 hours	Within 12 hours of onset of typical ischemic chest pain with ECG evidence of ST-elevation or pathological Q waves	Decreased blood levels of creatine kinase if propranolol given within 4 hours of onset of symptoms
Pelides et al	Practolol	I V [illegible]0 mg	Up to 72 hours after onset of symptoms	Decrease of area and severity of ST elevation
Barber et al.	Practolol	Orally 300 mg b d	As soon as patient seen and then for [illegible] years	If initial heart rate exceeded 100 per min., mortality reduced at 3 months
Waagstein and Hjalmarson [15]	Practolol	I V 5-30 mg (mean = 18 mg)	In coronary care unit as soon as possible after arrival	1 Dramatic pain relief 2. Double product fell from 10 500 to 8,500 3 ST segment fell by 29%
Waagstein and Hjalmarson [15]	Metoprolol	I V 15 mg	In coronary care unit as soon as possible after arrival	Similar effects to practolol but lower heart rate
Mulholland and Pantridge	Sotalol	I V 10 mg plus atropine 0 6 mg I V	Before transport by ambulance	Prevention of tachycardia (110-1?0 per min) during movement by ambulance better than practolol
Devlin et al	Sotalol	I V 10 mg	Before transport by ambulance	Normal pre movement heart rate kept low
Heikkila and Nieminen	Pindolol	I V 0.2 mg	Within 15 hrs. of onset	Improves systolic wall motion by echocardiography

Double product = systolic BP × heart rate I V = intravenous.

below) it is not surprising that the majority of animal experimental work shows that propranolol can substantially reduce the extent of ischemic injury and of myocardial necrosis [3] [4] (see also Opie and Thomas [2]) although there is no ready explanation for one discordant study [6] in which propranolol in a high dose (5 mg /kg) had no effect That study is especially difficult to understand because the same group found that propranolol reduced enzyme release in patients with infarction (see Table II) Other studies [5] show that propranolol decreases the extent of enzyme depletion and the development of epicardial Q waves in the infarcting dog heart However a possible disadvantage of propranolol is the decreased coronary perfusion pressure which might explain why propranolol decreased the coronary flow in the ischemic zone of open-chest anesthetized dogs [4] [31] [8] The most recent information from closed chest conscious dogs [3] indicates that propranolol causes a favorable redistribution of the blood supply to the ischemic area important hemodynamic differences from open chest preparations are the greater decrease of heart rate in open chest dogs (higher pre propranolol rate) and the lesser cardiac dilatation following propranolol in closed chest dogs [39]

In patients flow to the ischemic zone cannot directly be measured but indirect evidence suggests that propranolol improves the coronary flow relative to the metabolic demand [10] Thus propranolol can be expected to have a beneficial effect on the infarcting myocardium unless there is heart failure when the heart can be expected to enlarge further as a result of decreased contractility

Metabolic effects of β blockade Tissue necrosis ultimately depends on cellular metabolic

practolol given to patients with an initial heart rate exceeding 100 per minute improved the short term prognosis (Table II) A high heart rate during movement by ambulance can be prevented by sotalol (10 mg intravenously alone or with atropine 0 6 mg)[153, 154] but an effect on ischemic injury was not proven A randomized study in other situations—e g patients without heart failure in Killip groups 1 and 2—with positive effects on mortality would be required before β blockade could be recommended in other situations

β blockade Summary The use of β blockade to limit ischemic damage in acute myocardial infarction has extensive experimental and clinical support One report suggests that infarct size is limited in patients as shown by decreased rates of release of creatine kinase Certain contraindications require strict observation to avoid undesirable side effects Close monitoring of the patient is required Both mechanical and metabolic factors may account for the improvements observed There are insufficient data to recommend the general use of β blockade in patients with acute infarction

2 Metabolic interventions—Glucose insulin potassium (GIK)

GIK as a polarizing agent Although GIK is now known to have a metabolic action very similar to that of propranolol (compare Opie and Thomas[3] with Opie and Stubbs[1]) GIK was first popularized by Sodi Pallares and his group[1] as a polarizing agent that could restore K loss from the ischemic zone and hence improve mitochondrial function Their claim of improved K in the ischemic zone after experimental coronary occlusion has been questioned by Surawicz[1] but there is no real reason to doubt that K uptake can occur[6, 7] and that tissue K can improve Sodi Pallares work led to the expectation that GIK could reduce arrhythmias in patients with acute infarction but numerous contradictory studies were conducted before the recent description of the natural history of arrhythmias in acute myocardial infarction led to the knowledge that by far the majority of lethal ventricular arrhythmias (fibrillation) occur within the first 5 hours of the onset of symptoms[3] —i e before GIK was instituted in those studies The antiarrhythmic effects of GIK have now been shown by Lown s group[1] who found that GIK elevated the ventricular fibrillation threshold in dogs

Metabolic effects of GIK More recently [illegible] studies have shown that GIK can inhibit myocardial necrosis[1] as effectively as other anti inf[illegible] agents such as hyaluronidase[1] In the babo[illegible] GIK helps to minimize ischemic tissue metab[illegible] changes such as depletion of high energy phosphate compounds and of glycogen[161] Opie a[illegible] Owen[60] studied the metabolic effects of GIK [illegible] found that it was especially effective on th[illegible] border zone of the developing infarct when g[illegible] for 6 hours after coronary artery ligation How[illegible] er it was also striking that GIK increased glycogen in all infarct zones and according to s[illegible] workers the ultimate degree of necrosis is ver[illegible] closely linked to the degree of cardiac glycog[illegible] retention[135] Thus it may be that when given ov[illegible] a longer period than 6 hours GIK is able t[illegible] protect all zones against developing infarction I[illegible] should be stressed that GIK did *not* cause [illegible] accumulation of lactate or protons in th[illegible] ischemic tissue[161] in spite of the theoretical h[illegible]ard of this supposed side effect[16]

The cellular metabolic effects of GIK in dev[illegible]oping infarction were as follows[60] The extracti[illegible] of glucose increased relative to that of free fat[illegible] acid cardiac glycogen increased and there was a switch from the metabolism of free fatty acid to that of glucose with decreased ST segment eleva[illegible]tion similar metabolic effects can be achieved by propranolol in dogs[13] and in man[1]

To measure the maximal possible degree of conservation of oxygen induced by glucose in[illegible]lin potassium we examined GIK effects on a isolated perfused rat heart preparation (Table IV) After coronary artery ligation the extent of the ischemic zone was measured by a suprav[illegible] dye and by the severity of enzyme release Cha[illegible]ing the perfusate from a low potassium (3 0 mM) fatty acid solution to the addition of glucose insulin potassium (K = 5 9 mM) greatly d[illegible]creased the release of enzyme and the appar[illegible] size of the ischemic zone while the mechanical efficiency (measured as joules/ml oxygen utili[illegible]tion) was increased Thus compared with [illegible] fatty acid utilization at a low perfusate K GI[illegible] markedly spared oxygen by improving effici[illegible] by 60% Similarly excess FFA caused a [illegible] deterioration of efficiency in nonischemic [illegible]lated pig hearts[163] Although these data are n[illegible] necessarily applicable to the more complex [illegible] bolic situation in patients[1] yet the principle of [illegible]bolic situation in patients yet the principle of metabolic oxygen wastage" and mechanical inefficiency is stressed

when propranolol was given within 4 hours of the onset of symptoms and even then was of borderline significance ($P < 0.05$ $2P < 0.1$—usually it is the two tailed value for P which is quoted)

β blocking agents other than propranolol (Table II) Patient studies with β blocking agents other than propranolol are also shown in Table II and again the beneficial effects are apparent but again data on infarct size are missing The agent best researched in man practolol reduces pain ST elevation and short term mortality in patients with an initial heart rate exceeding 100 per minute [45] when practolol is started at a dose of 300 mg every 12 hours within 3 hours (median value) of the onset of symptoms Although practolol has undesirable side effects with long term usage there would appear to be no reason why short term practolol should not be used to institute treatment to be followed by another β blocking agent Another cardiospecific β blocker metoprolol also reduces pain and ST elevation when given *intravenously in the early stages* of myocardial infarction (see Table II)

The long term beneficial effect of β blockade in reducing sudden death after anterior myocardial infarction has been shown for practolol[48] similar data exist for alprenolol[49] which like practolol possesses intrinsic sympathetic activity But in neither study could the long term effects be ascribed to reduction of infarct size because the β blockade was started after the acute phase was over Theoretically it is incorrect to extrapolate from results obtained with practolol to results that might be expected with another β blocking agent such as propranolol which has no intrinsic sympathetic activity It remains possible that the presence and amount of intrinsic sympathetic activity is important in secondary prevention and it could be argued that only agents with such activity should be used for situations in which practolol has proved effective Other agents with intrinsic activity include oxprenolol pindolol alprenolol and acebutolol but the amount of intrinsic activity varies Because of the different properties of different β blocking agents it has been argued that it is unethical to promote drugs other than the tested ones (practolol alprenolol) for post infarct protection and the same arguments should hold for the acute phase

Sowton and associates and Shanks [31] have argued that it is the β blocking qualities which are of most importance and that additional qualities are of no real therapeutic significance Although many clinicians seem to feel that the use of agents with intrinsic sympathetic activity *in acute myocardial infarction leads to fewer* problems with bradycardia documentation of this theoretically possible view is not yet available Very recently a challenging research report suggests that dimethylpropranolol an agent without β blocking activity can protect against ischemic reperfusion damage [15]

Contraindications to β blockade (Table III) Each of the above cited studies used certain definite contraindications as listed in Table III It is of interest that the majority of workers did not require monitoring by invasive procedures such as Swan Ganz catheterization or measurements of the cardiac index to assess whether beta blockade should be instituted or discontinued

β blockade Claims and counterclaims In brief β blockade given in the acute phase is claimed to counteract the manifestations of acute ischemia and to improve the short term prognosis in patients. Studies on the effects of infarct size in patients are not yet at hand *although the rate of* release of creatine kinase may be diminished by propranolol (P values borderline by one method of analysis) [1]

The major arguments against the use of β blockade therapy rest on the possible harmful side effects Occasional patients may develop high grade heart block requiring a pacemaker and the dangers of hypotension or heart failure also exist One of 95 patients treated by Peter and associates [5] required balloon counterpulsation for heart failure thought to be precipitated by propranolol Although these side effects are rare especially in closely monitored and carefully selected patients they are all too visible in comparison with the invisible effects of reduction of infarct size Whether such potential side effects of β blockade are real hazards, awaits further studies The decision whether or not to use β blockade in a given patient must depend largely on the skill and discretion of the attending physician and his views on the desirability of reduction of ischemic injury and (possibly) infarct size and on the status of the patient (Table III) In view of the harmful effect of a high heart rate on ischemia (see Fig 4 Part I) it is theoretically desirable to reduce a tachycardia not caused by heart failure or infection i.e an inappropriate tachycardia Support for this view stems from the observations of Barber and colleagues[1] that oral

electrical stimulation of the heart with acute coronary occlusion

However, recently Heng and colleagues[163] showed that when high blood glucose values of 400 to 600 mg/100 ml were maintained in patients with acute myocardial infarction infarct size failed to decrease which is not surprising because the high blood glucose must be acting as a positive inotropic agent[177] Thus, when GIK is given extreme hyperglycemia should be avoided unless the inotropic effect is specifically desired In patients Sodi Pallares[178] recommended blood glucose values of between 120 and 140 mg/100 ml but tolerated values between 70 and 160 mg/100 ml However higher values of an average of 286 mg/100 ml were accepted by Rogers and co workers[16]

GIK and infarct size The study of Heng and associates[163] is one of the only two studies that have measured infarct size The numbers studied by Heng and colleagues[163] were too few to permit any firm conclusions as also conceded by the authors Furthermore the time after the onset of symptoms and the infarct size were too variable to allow tight grouping of the patients A larger randomized trial assessing the effects of GIK, is now underway[180] and may give clearer guidance on the possible value of GIK in acute myocardial infarction Present indications are that GIK reduced circulating free fatty acids and both the incidence of ventricular premature systoles and ventricular tachycardia survival appeared to improve but enzymatically estimated infarct size did not change However the major rise of free fatty acids occurs in the first 6 to 8 hours of the onset of symptoms[79] thus only when GIK is given very early could oxygen sparing' be expected

GIK Claims and counterclaims Although one nonrandomized trial[16] strongly suggests that GIK may improve mortality rate in patients with infarction Heng and co workers[163] felt impelled to stop their much smaller trial However they did not consider that excess hyperglycemia (see above) could be adversely affecting the development of the infarction by increasing heart work (mean arterial pressure and pulmonary artery end-diastolic pressure increased) in their study In fact the data of Heng and associates[163] could be interpreted to show that GIK may be a useful agent when an inotropic agent is required which appears not to extend infarct size even this conclusion cannot be reached with certainty on the basis of the small numbers studied by Heng and colleagues[163] but it is in keeping with careful ly documented dog data[173] and with ventricular function studies in patients[181]

Another situation for which GIK should be considered is the presence of severe heart failure with a low sodium syndrome[18]

GIK was also reported as reducing the incidence of heart block in an uncontrolled study but the potassium in GIK can promote prolonged A V conduction in normal subjects at even normal potassium levels[184] Thus more observations are required on patients with heart block

GIK Summary GIK has attracted considerable attention as being one of the first anti infarct agents studied. Experimental evidence shows that GIK reduces infarct size GIK has some propranolol like effects on heart metabolism including oxygen conservation The majority of clinical studies have not been conducted in the light of modern knowledge of the natural history of arrhythmias and the patterns of development of infarct size occurring after the onset of acute myocardial infarction nor has the effect on infarct size been assessed in most studies in man The results of a randomized study now underway will give better guidance on the possible use of GIK in acute myocardial infarction GIK may have a place as an inotropic agent not increasing infarct size

3 Reduction of the load on the heart and increased collateral flow by nitrates

Nitrates coronary vasodilation vs load reduction Amyl nitrite was used at the end of the last century for relief of angina by Lauder Brunton, who noted the association of increased arterial pressure with the anginal attack and found that amyl nitrite relieved the pain and decreased the arterial pressure Many years later Robinson found that for a given patient the double product of heart rate and systolic pressure required for the production of angina was relatively constant He concluded that the advantage of the hypotensive action of nitrate outweighed its action in producing tachycardia Furthermore venodilation was held to be the cause of decreased left ventricular end-diastolic pressure[14] It is evident that apart from the tachycardia nitrates produce reduction of the preload and the afterload changes which should be conducive not only to

Electrocardiographic effects of GIK Two experiments published by Calva and colleagues[6] are of particular historical interest because they antedate the current interest in the epicardial electrocardiogram generated by the work of Maroko and Braunwald.[6] In the GIK treated heart in spite of the ST-elevation initially being greater the final Q wave formation was less.

GIK dosage Although Sodi Pallares has had extensive experience of GIK in patients neither his work nor the MRC trial[16] were conducted in conditions which are directly relevant to our modern knowledge of the development of acute myocardial infarction. Thus in the MRC trial the average time elapsed since the onset of symptoms and the start of the GIK infusion was 24 hours or more in nearly 90% of patients by which time infarct size may largely be fixed (although reinfarction can still occur); furthermore the doses used were low and the glucose was sometimes given orally and the insulin subcutaneously (see Table V). Rogers and associates[6] Thus the effects of intravenous GIK in the early phases of acute myocardial infarction require assessment. Rogers and co workers[6] have shown that GIK (given into the right atrium as 300 g glucose, 80 mEq potassium, and 50 units soluble insulin per liter at the rate of 1.5 ml/kg/hr) is very effective in bringing down circulating free fatty acids in patients. When GIK was given for 4 days it induced potassium gain and elevation of blood glucose. This investigating team noted a transient hyperkalemia in some instances[6] and also found that the pulmonary wedge pressure did not rise with GIK treatment. It would nevertheless be important to search for GIK effects on pulmonary capillary wedge pressure in patients with left ventricular failure. The problem of hyperkalemia would be avoided by a variable potassium infusion as recommended by Sodi Pallares and Ponce de Leon.[1]

GIK as an anti lipolytic intervention Thus reduction of plasma free fatty acids is an important effect of GIK (Table IV). Lipolysis can also be inhibited by a *nicotinic acid analog*. In pacing induced angina the degree of ST depression (but not the development of chest pain) was reduced as the circulating free fatty acids fell. This intervention also reduces acute ischemic injury in patients with infarction as judged by decreased precordial ST elevation and decreased arrhythmias.[1] However repetitive use of this agent throughout the first 24 hours of acute myocardial infarction cannot be recommended because the blood free fatty acid values rebound[1] unless high doses are used which cause significant side effects. In contrast GIK can consistently depress circulating free fatty acid values in patients with infarction without side effects or rebound.[6,1] In addition however both GIK[173] and addition of glucose[79] can achieve their effects in the presence of unchanged circulating free fatty acid levels showing that GIK acts not only as an antilipolytic agent but also by promotion of glucose metabolism in animal models.

Table IV GIK and efficiency of rat heart compared with effects of very high fatty acid low K perfusate (Opie and Bricknell unpublished data)

	Efficiency (Joules per ml O₂)	*Enzyme release (mU/g/hr)*
Hearts perfused with pathologically high fatty acid and low K, K = 3.0 mM	3.10 ± 0.09 (45)	33,058 ± 3,397 (14)
Hearts perfused with glucose and insulin, K = 5.9 mM	4.93 ± 0.09 (55)	6,699 ± 329 (7)
Change	+60%	−80%

Effects of changing from low K high fatty acid perfusate to GIK (as glucose 11 mM, insulin 2 mU/ml, K = 5.9 mM) in isolated perfused working rat heart with coronary ligation. Efficiency was measured by comparing the oxygen uptake with the work performance. Enzyme release was taken as an index of ischemic damage and was measured as release of lactate dehydrogenase from the coronary venous effluent. The mechanism of the altered efficiency induced by these extreme alterations of substrate (high fatty acid to GIK) is unknown but may include oxygen wasting. Note that as efficiency rises with GIK enzyme release is greatly decreased. Mean values ± SEM.

Danger of hyperglycemia Maroko and co workers found that hypertonic glucose by itself was nearly as effective as GIK in preventing necrosis after coronary occlusion in dogs. It is however important to note that the blood glucose concentration should not be allowed to rise to values which are too high. Sonnenblick and colleagues injected hypertonic glucose into dogs shortly after coronary artery ligation; the blood sugar rose to values of nearly 700 mg/100 ml while the contractility of the heart increased and the elevated end-diastolic pressure fell. The therapy reduced the incidence of ventricular premature beats and of ventricular fibrillation. The beneficial effect of hypertonic glucose on arrhythmias has been confirmed[17] in that intravenous glucose prevents the onset of ectopic beats after

Table V Mechanism of action of four anti infarct agents based on experimental data and/or clinical observations

	Heart rate	*BP*	*Contractility*	*Afterload*	*Metabolism*	*Microvascular damage*	*Blood flow*
Propranolol	↓	↓	↓	↓	Yes	Yes	Redistribution
GIK[b]	Small increase	No	↑	No	Yes	No data	Increases coronary and out flow in man
Nitrates	No	↓	No	↓	No data	No data	Yes
Hyaluronidase[d]	No	No	No	No	No data	No data	Yes

nally drew attention to the beneficial hemodynamic effects of afterload reduction in patients with left ventricular failure and acute myocardial infarction[199] Experimentally nitroprusside is more potent than nitroglycerin in decreasing systemic arterial pressure but less potent in increasing collateral flow as assessed by the retrograde blood flow method[49] while nitroprusside actually reduced collateral flow as assessed by microspheres[200] The effects of nitroprusside on ST segment changes are controversial both in animals and in man (see Table I) unfavorable effects may reflect excess hypotension with reduction of post stenotic coronary flow (Table I including Ref 244) In patients nitroprusside is more effective than intravenous nitroglycerin in reducing the peripheral vascular resistance [1] and hence would probably be the agent of choice in a hypertensive crisis complicating acute myocardial infarction However the balance of experimental evidence suggests that nitrates are more effective than nitroprusside in maintaining flow to the ischemic myocardium [0] The comparable effects of nitroprusside and nitroglycerin on infarct size in patients with predominant arterial hypertension and infarction requires assessment

Nitrates claims and counterclaims Present evidence suggests that oral or sublingual nitrates are a desirable therapeutic agent to reduce myocardial ischemic damage in the presence of left ventricular failure or possibly hypertension In patients without severe left heart failure hypotension tachycardia and even bradycardia are possible and unpredictable side effects with sublingual nitroglycerin[91] the addition of phenylephrine to avoid hypertension in patients without heart failure is disputed[193] Such harmful side effects have not been reported with intravenous nitrates which can be given even in the absence of left ventricular failure[193] but require careful hemodynamic monitoring Thusfar sublingual nitrates have been reported to have only beneficial effects when given to patients with severe left ventricular failure or pulmonary edema[193] However much more knowledge is required about the effects of nitrates on indices of infarct size and mortality as opposed to effects on ischemic damage (ST elevation) and about the comparative effects of nitrate and nitroprusside therapy in patients with hypertension

Nitrates Summary Nitrates have a triple action reduction of preload coronary vasodilation and afterload reduction Substantial hemodynamic evidence shows the benefit of nitrates including sublingual nitroglycerin in patients with acute myocardial infarction complicated by left heart failure but controversy surrounds the use of sublingual nitrates in patients without evident left ventricular failure In comparison with nitroprusside nitrates cause a greater reduction of the preload and a more consistent increase of collateral flow to the ischemic zone but a lesser effect in afterload reduction Critical studies showing an effect of nitrates in reducing infarct size in patients are not yet available

4 Increased diffusion to ischemic zone by hyaluronidase

Hyaluronidase was one of the first agents described as improving the consequences of coronary artery occlusion[203] but its mode of action by improving collateral flow is still only presumed Its introduction into clinical therapy

amelioration of anginal pain but to reduction of myocardial infarct size

Recent evidence supports the hypothesis that nitroglycerin acts as a true coronary vasodilator in dog preparations Becker and colleagues[18] found a favorable redistribution of coronary flow to the more ischemic subendocardial regions Epstein s group[9] have shown that when nitro glycerin is given with methoxamine[9] to keep heart rate and mean arterial pressure constant then the collateral flow is substantially increased while Bache[189] found that nitroglycerin infusion could increase blood flow to the central ischemic zone but could not exclude a primary effect on the transmural pressure

Nitroglycerin and acute ischemic injury The work of Epstein and co workers[190] has shown that sublingual nitroglycerin when given to selected patients with acute myocardial infarction may reduce precordial ST elevation However sublin gual nitroglycerin can in some patients cause a serious fall in the arterial pressure[191] and the resultant reflex tachycardia could theoretically increase ST elevation These effects can largely be avoided by limiting the use of sublingual nitrates to patients with left heart failure[192] Thus in acute pulmonary edema repetitive sublingual nitroglycerin was strikingly effective when em ployed as sole therapy,[19, A] emphasizing that although nitroglycerin reduces the afterload a more significant effect is reduction of the pre load[18, B] Although the simultaneous administra tion of an α stimulant such as phenylephrine is claimed to reduce the harmful side effects of nitroglycerin in patients without left ventricular failure[1] others find that added phenylephrine is harmful[193] Hence sublingual nitrates should be restricted to those patients with left ventricular failure in whom the prime aim of therapy is relief of failure and in whom reduction of infarct size is only a secondary aim

But nitroglycerin by infusion reduces the arte rial pressure without a tachycardia but with a decreased left ventricular filling pressure and decreased precordial ST elevation[1] These bene ficial effects were also evident in patients without left ventricular failure suggesting that intrave nous nitroglycerin is a more desirable agent than is the sublingual form for the reduction of ischemic injury possibly because the intravenous route allows finer regulation of hemodynamic effects

Another promising route of administration of nitroglycerin is percutaneously A theoretical advantage of the ointment would be that if the blood pressure fell too much the agent could simply be wiped off the chest This simple proce dure must merit intensive investigation in acute myocardial infarction

Nitroglycerin and infarct size Thusfar neither experimental nor clinical studies have been reported on the effect of nitroglycerin on infarct size But in dogs given both nitroglycerin infusion and methoxamine (to prevent hypotension and tachycardia), creatine kinase depletion de creased[90] A preliminary clinical report sug gests that an infusion of nitroglycerin at 50 μg/minute could limit R wave fall and decrease mortality rate

Long acting nitrates Long acting nitrates have for long been thought to have no special advantage over the sublingual nitrate in the treatment of angina Recently the drug isosorbide dinitrate has been studied in patients with acute myocardial infarction[97] An immediate dose of 10 mg orally was followed by 20 mg 1 hour later Left ventricular filling pressure fell, but in those patients who had no left ventricular failure the cardiac output stayed the same or fell whereas in those patients with left ventricular failure (de fined as a left ventricular filling pressure exceed ing 20 mm. Hg) the cardiac output usually rose The effects were noted up to 9 hours after the control observation i.e up to 8 hours after the second dose of isosorbide dinitrate These workers did not assess infarct size but the hemodynamic changes reported for patients with left ventricular failure are those which could be expected to improve ischemic injury

Nitrates and coronary vasospasm Maseri and associates[4] have proposed an important role for coronary vasospasm in the production of angina One recent report[12] suggests that arterial spasm is present in nearly half the patients studied within 12 hours of the onset of symptoms of myocardial infarction Nitrates relieved the coronary vaso spasm which is a further argument for the evalu ation of nitrates as anti infarct agents For relief of vasospasm nitrates would require comparison with α blocking agents[1, 3] and calcium antago nists[110]

Nitrates versus nitroprusside The effects of nitrates may be compared with those of nitro prusside, the agent used in the work which origi

Table VI Effect of four anti infarct agents on various stages of experimental myocardial infarction

	Ischemic injury (ST elevation)	*Necrosis (Q formation or histology)*	*Wound healing*
Propranolol	Yes	Yes	No data
GIK	Yes	Yes [illegible]	Conflicting data
Nitrates	Yes	Preliminary data [illegible]	No data
Hyaluronidase	No data	Yes [illegible]	Yes

In patients the comparative efficacy of the four anti infarct agents can be assessed by their effects on pain relief the precordial electrocardiogram (ST-elevation or Q formation), mortality rate and long term post infarct prognosis (Table VII) β blockade is effective against the widest spectrum of features of acute myocardial infarction only effects on Q wave formation have not yet been shown (no data)

It is very important to note that only β blockade has thusfar been shown to influence mortality rate in patients with acute myocardial infarction and that the only data available are for practolol given in specific circumstances (given to patients with initial heart rate exceeding 100 beats per minute within a median value of 3 hours of onset see Barber et al [116]) Although there are strongly suggestive data for GIK [15] a randomized study is essential The general lack of data on the effects of anti infarct agents on mortality rate is not because such effects could not be expected but probably because of the large numbers of patients required to show reduced mortality rate

Harmful effects and contraindications Among the possible harmful effects of anti infarct agents are the provocation of heart failure hypotension tachycardia or fluid and electrolyte problems (Table VIII) Judged by these criteria hyaluronidase is the safest agent followed by GIK Any adverse effects of GIK should be greatly limited by modern technology which can give a bedside glucose and potassium reading within minutes Oral nitrates can cause hypotension and tachycardia β blockade can cause heart failure hypotension and heart block The exact incidence of these side effects will only become known in time but careful patient selection should minimize undesirable effects In selected conditions either nitrates or β blockade are safe the effects of combinations are unknown although the opposing effects on the heart [illegible] suggest the possibility of therapeutic combi[illegible] tion

Thus, after due consideration of the contra[illegible] cations β blockade can be used intravenou[illegible] a coronary care unit with appropriate mon[illegible] (oscilloscope and some would say a Swan Ga[illegible] catheter) provided that the drug is given slow[illegible] β blockade can be given orally in the hosp[illegible] outside of the coronary care unit The use of GI[illegible] requires monitoring of blood glucose and pota[illegible] sium values which can be done not only in [illegible] coronary care unit but also in the general hosp[illegible] setting The use of nitrates also requires hemod[illegible] namic monitoring in the coronary care u[illegible] However long acting oral nitrates could be gi[illegible] to patients in the general hospital if heart fa[illegible] were present Although hyaluronidase [illegible] appear to be an agent safe enough for use in t[illegible] coronary care unit or in the general hospital [illegible] even outside the hospital it is stressed that [illegible] use of anti infarct agents by physicians [illegible] seeing a patient outside the hospital still requ[illegible] clinical trial

6 Ideal heart rate and blood pressure

It is sometimes *inferred* that ischemic dam[illegible] has extended or regressed by measurements of [illegible] determinants of the myocardial oxygen up[illegible] The argument is as follows If the afterload [illegible] reduced oxygen uptake will fall and ische[illegible] injury will decrease Supposing that an interv[illegible] tion reduces the blood pressure from 160 to [illegible] mm Hg systolic and the heart rate from 110 [illegible] beats per minute then the double prod[illegible] halved the myocardial oxygen demand ma[illegible] halved and one could infer that there should [illegible] substantial reduction in ischemic injury [illegible] hence in the ultimate infarct size provided t[illegible] all other factors are equal

As far as *heart rate* is concerned this argu[illegible]

tics stems from the experimental observations of Maroko s group [2, 114] who have shown that hyaluronidase can reduce infarct size and can counter the development of the Q wave in dogs with coronary ligation Unexpectedly hyaluronidase is not effective in the pig model [65] which presumably reflects the necessity for a patent collateral circulation for the action of an anti infarct agent to be manifest [31] The pig is thought to have a poorly developed collateral circulation

Hyaluronidase is one of the few agents which has been shown to counter the electrocardiographic signs of necrosis in patients with anterior myocardial infarction of less than 8 hours duration by inhibition of loss of the R wave and formation of the Q wave In that study [69] hyaluronidase was given as 500 units/kilogram intravenously as a bolus every 6 hours for 48 hours After a negative intradermal test (100 units intradermally observed for 5 minutes) 46 treated patients were compared with 45 control patients Nine patients were excluded because of an allergic reaction i e 9/100 or 9% of patients Patients with QRS prolongation or left anterior hemiblock were excluded not because it was feared that hyaluronidase could adversely influence such cases but because the assessment of the ECG signs of evolving infarction might have been obscured If the effect of hyaluronidase on necrosis could be extrapolated from the changes induced in the QRS pattern of the precordial electrocardiogram as in the case of dogs with coronary occlusion [23] then the degree of reduction of necrosis by hyaluronidase was about 24% (comparing the evolution of ΣR over 7 days in control with treated patients) This may be considered disappointing compared with the 45% reduction of necrosis in dogs achieved by hyaluronidase The difference could be explained by the fact that some of the patients in the hyaluronidase trial probably did not have an adequate coronary collateral circulation and therefore would be less responsive to therapy

However the above study does not allow the firm recommendation to be made that hyaluronidase should be given to all patients seen early enough in the acute stage of myocardial infarction A further trial including those patients whose ECG changes did not allow them to be included in the first trial (e g patients with posterior infarction) with long term follow up is required before such a conclusion can be made

Mode of action of hyaluronidase Hyaluronidase increases coronary collateral flow [2, 7] prevents the reduction of coronary flow induced by ischemia and counteracts the formation of edema fluid as ischemia progresses [2, 4] It would seem that the combinations of hyaluronidase with other anti infarct measures warrants experimental assessment

Hyaluronidase Summary Hyaluronidase has been carefully studied in a wide range of experimental preparations and has been shown to reduce ECG features of necrosis in selected patients with acute myocardial infarction Thus far no undesirable side effects have been reported except for allergy Further clinical trials are required before a general recommendation for use of this agent can be made

5 Comparative effects of the four selected antiinfarct agents (Table V)

Mechanism of action The comparative mechanism of action of the four anti infarct agents selected in this review are shown in Table V Of the agents β blockade is the only one acting on all the following parameters heart rate blood pressure contractility metabolism and coronary blood flow In addition propranolol decreases microvascular damage [6] GIK improves the metabolism and in doses giving marked hyperglycemia increases indices of contractility while not extending infarct size Nitrates act chiefly by decreasing the load but also by a blood flow effect Hyaluronidase is the only agent with no known effect on the mechanical behavior of the heart Hyaluronidase is thought to act by improved blood flow and only secondarily by improved tissue metabolism

The four agents considered act differently on the three stages of development of the experimental infarct ischemic injury development of necrosis and wound healing (Table VI) All agents are effective against early ischemic injury as judged by effects on the degree of ST elevation on the epicardial electrocardiogram All agents are effective against necrosis as judged by Q wave formation on the epicardial ECG or by histology only hyaluronidase[115] and possibly GIK have been shown to accelerate wound healing [11] (but see Ahmed et al [73]) These experimental criteria do not allow conclusions as to which agent would be the most effective in limiting ultimate infarct size

approximations of changes in ischemic injury For more precise evaluations of the effects of anti infarct agents measurements of precordial ECG changes or enzyme release patterns would be required

7 Timing of intervention

A further critical point is to know when to intervene Table IX shows that some interventions can be effective as judged by ST segment criteria up to 72 hours after coronary occlusion or the onset of symptoms Most animal work has been done within hours of the onset of coronary occlusion with the exception of exaggeration of enzyme release by isoproterenol[74] However the interpretation of those data based on increased liberation of creatine kinase up to 72 hours after coronary occlusion in dogs must be regarded with some reserve because of the capacity of excess β stimulation to cause release of enzymes even from an apparently normal heart[14] Nevertheless Shillingford and his group[117] found that β blocking agents could decrease ST-elevation up to 72 hours after the onset of symptoms in patients with myocardial infarction (Table IX) suggesting a prolonged effect of β stimulation Increased urine catecholamine secretion values are found up to 4 days after the onset of symptoms in some patients[1] Pelides and associates[113] restudied three patients at increasing times after the onset of symptoms and although there was a decreasing effect at the second study nevertheless they still obtained a decreased ST elevation and decreased precordial area of ST elevation

However chronic therapy (started before the infarct developed) with β blockade in patients with acute infarction can decrease ST elevation without altering the rate of Q wave formation[1]

Some of the above data suggest that it would seem reasonable to intervene with β blockade up to 72 hours or with afterload reduction (nitrates trimethaphan) 8 to 14 hours after the onset of symptoms On the other hand the data showing favorable electrocardiographic effects on necrosis (assessed by QRS changes) of hyaluronidase in patients were obtained within 8 hours after the onset (mean 4 6 hours) An important finding with hyaluronidase (given to dogs as a single bolus) was that it had to be given within 6 hours after experimental coronary occlusion and it had no effect 9 hours after coronary occlusion[114] Similarly propranolol had to be given within 4 hours of the onset of symptoms to be effective reducing enzyme release[115] Practolol was give within 3 hours (median) of onset of symptoms b Barber and co workers[116] Selwyn and associa studied the rate of evolution of Q wave cha and found that complete development took 6 to 12 hours Thus from many points of vi interventions should ideally start within 6 ho of the onset of symptoms

Conclusions There is no unanimity on the timing of the interventions Some data sug that anti infarct agents could be given m hours after the onset of symptoms Clearly how ever the sooner after the onset of symptoms t therapy is given the better Data with propra lol and hyaluronidase suggest that a delay of 4 8 hours (respectively) is the maximum that can b tolerated

8 Anticipated effects of commonly used agents on ischemic injury of infarct size in patients

Among agents frequently used in the therap acute myocardial infarction are heparin an ox gen mask antiarrhythmic agents such as li caine and anti failure drugs such as digita diuretics and aminophylline and agents a pain such as morphine It may be that each these agents may influence ischemic injury a or infarct size

Heparin is frequently used in acute myocardi infarction for its supposed effects in preven venous thrombosis and possibly in stopping t formation of arterial thrombosis The b action has not been well documented but wo be logical if the actual coronary thrombo (when present) has a stuttering or delayed or as originally suggested by clinical work as originally suggested by clinical work Heparin recently confirmed experimentally Heparin d creases signs of ischemic injury and lessens th necrosis when given following coronary art ligation in the dog and decreases ST segme elevation in patients[16] Hence it would be log to test the effect on infarct size Howeve cautionary note is needed Since heparin incre blood free fatty acids this action must to so extent antagonize the antithrombotic and a platelet effects of heparin

Increased arterial oxygen receives support f its use because on 100% oxygen patients e denced decreased precordial ST segmental ele

ppears to be valid In closed chest dogs the verity of ischemic injury as judged by ST evation was directly related to the heart rate ver the range 30 to 215 beats per minute[7] hereas an increased heart rate induced by atrial acing increased estimated infarct size in dogs by 0%[7] (For the possible effects of atropine in voiding the dangers of bradyarrhythmias see ection 8)

However as far as *blood pressure* is concerned he oxygen sparing effect of hypotension induced y hemorrhage appears to be outweighed by the armful effects of decreased coronary perfusion ressure[15] Hence it would follow that hypoten ion plus bradycardia requires atropine treat nent but bradycardia without hypotension or eart block does not require therapy The ideal ypotensive agents should therefore be those hat at the same time will decrease arterial ressure but also protect the ischemic myocar lium from underperfusion Both β blockade and itrates may do this by redistribution of blood low and vasodilation respectively Conversely in increased blood pressure increases ischemic njury and infarct size Even systolic blood pres ures of 150 to 165 mm Hg gave rise to infarcts bout one quarter larger than did pressures educed by about 30 to 40 mm Hg[3] although the se of computer predicted infarct sizes is open to some question

The *ideal blood pressure* in acute myocardial nfarction has not been determined but in the case of patients treated by intravenous proprano lol[140] the blood pressure could be reduced from an initial mean arterial pressure of 92 to only 76 mm Hg Similarly intravenous nitroglycerin could reduce blood pressure from a mean of 108 to 87 mm Hg[19] while ST segment elevation decreased Thus it seems as if patients with acute myocardial infarction can tolerate relatively low heart rates and blood pressures and that such values may beneficially influence ischemic injury and infarct size However blood pressure reduction achieved by agents such as nitroprusside and diazoxide which do not at the same time increase collateral flow need not always be beneficial but may be harmful[2 00 20 21]

The effects of increases in *heart rate or blood pressure have been compared* in patients with fixed coronary obstruction[2 3] Tachycardia was more harmful than hypertension as judged by increased chest pain and ST segment changes despite similar increases in myocardial oxygen consumption In the case of metabolically active agents such as GIK the heart rate and blood pressure cannot be used to assess any *oxygen sparing effect* nor can any metabolic effect of β blockade thus be assessed Nor can the effects of complex interactions in patients with left ventricular failure and/or dilated hearts be so assessed Indirect estimates of hemodynamic per formance also give no idea of the effects of hyaluronidase which does not influence hemody namic parameters Thus at present changes in the inferred indices of myocardial oxygen demand (heart rate blood pressure) can only give rough

Table IX Period of delay from onset of symptoms or coronary occlusion to intervention changing ischemic damage or infarct size

Intervention	*Period*	*Conditions*
A. *Decreasing ischemic damage*		
Nitroglycerin (IV)	Up to 21 hours (mean 8 hours)	After onset of symptoms in patients ST-changes
Practolol (IV)	5 72 hours (mean 31 hours)	Effect on precordial ST-elevation in patients
Practolol (IV) [1]	24 72 hours	Effect on pain in patients with acute myocardial infarction
B *Decreasing infarct size*		
Hyaluronidase	6 hours (9 hrs no effect)	Coronary occlusion in dogs
Propranolol	3 hours	Coronary occlusion in dogs
Propranolol	4 hours	Enzyme release in patients
GIK and propranolol [59]	3 hours	Coronary occlusion in dogs
Afterload reduction[a] (trimethaphan)	14 hours	After onset of symptoms in patients
C *Increasing infarct size*		
Isoprenolol	72 hours	Closed-chest dogs enzyme release
Digitalis	11 19 hours	After onset of symptoms enzyme release

A ganglion blocking agent
IV = intravenous administration

tion relief of pain and pulmonary edema should lead to decreased discharge of catecholamines [230] Although the possibility that morphine could cause arterial hypotension in some patients raises doubts about coronary perfusion the hypotensive effect appeared short lived and 15 minutes after the morphine baseline arterial values were regained [3]

Atropine when given for bradycardia, may avoid bradyarrhythmias which could increase infarct size by hypoperfusion On the other hand an atropine induced tachycardia could also increase infarct size The optimal lower limit of heart rate has not yet been defined

Commonly used agents Summary It is reassuring that many agents routinely used in the management of acute myocardial infarction are more likely to limit than to extend infarct size or ischemic injury with the exception of digitalis given to the nonfailing heart Aminophylline is probably harmful by provocation of arrhythmias

9 Can provisional guidelines to management of infarct size be given?

A distinction must be made between a general recommendation th t the time has not yet come to introduce anti inf r t agents into general cardiological prac ice nd recommendations for individual patients General recommendations could only be made once randomized trials have shown that relatively safe agents could decrease mortality rate or significantly change other complications of infarction That point has not been reached In the meantime the cardiologist faced with a patient with myocardial infarction needs to match existing data with the desire to do the best for the individual patient

Because it has been shown that larger infarcts are on the whole associated with a worse prognosis it would seem only prudent to avoid agents known or suspected of increasing myocardial infarct size The major agent is isoprenaline

Secondly *when complications call for treatment* those agents should be used which are thought to reduce infarct size everything else being equal For example if load reduction be required in the presence of left ventricular failure then currently available literature would suggest a role for nitrates (especially long acting oral compounds) to reduce the preload (and possibly the afterload)

Thirdly when there is clinical or laboratory evidence of reinfarction or extension of the infarction process the case for therapeutic intervention becomes stronger

Each agent has some arguments for a specific use Thus β blockade may be indicated for

Table VIII Possible harmful side effects of four anti infarct agents

tion[21] However the complex hemodynamic effects of oxygen in some patients[1] mean that ischemic damage would not necessarily improve

Lidocaine although given as an antiarrhythmic agent reduces epicardial ST elevation when given at a dose of 3 mg /kg in dogs with coronary occlusion[21] Lidocaine also reduces ischemic damage during cardiopulmonary bypass[22] Lidocaine decreased catecholamine induced enzyme release from the isolated perfused rat heart Lidocaine also improved myocardial blood flow by 60% in patients studied 15 days after acute myocardial infarction Thus lidocaine would probably improve ischemic damage but firm data are lacking

Verapamil is also primarily an antiarrhythmic drug used for supraventricular tachycardia but decreases experimental infarct size[10] possibly by selectively decreasing the contractility of the ischemic zone[2]

Disopyramide given orally (100 mg four times daily) as soon as possible after admission to hospital has very recently been reported to limit extension of infarction to decrease serious arrhythmias and to decrease mortality rate[2,3] The design of this study can be criticized chiefly because the control mortality rate was so high These observations therefore need confirmation but do suggest the feasibility of more effective therapy for patients not managed in a coronary care unit

Antiarrhythmic agents may therefore in general be held to have anti ischemic effects In addition to the effects of lidocaine verapamil and disopyramide β blockade has antiarrhythmic effects[1] as do nitrates Glucose insulin potassium is antiarrhythmic in dog infarcts[1] The mechanisms linking infarct size and arrhythmias are ill understood but it is reasonable to conclude that the use of antiarrhythmic agents will in general reduce infarct size and the use of anti infarct agents will in general reduce arrhythmias because patients with large infarcts also tend to have more arrhythmias[1]

Digitalis as acetyl strophanthidin when given to patients without overt heart failure 11 to 19 hours after the onset of symptoms could greatly increase infarct size as estimated by creatine kinase release curves[31] However animal data suggest that digitalis compounds when given in the presence of cardiomegaly could exert a beneficial effect on infarct development probably by reduction of heart size and myocardial oxygen demand[5] In the presence of uncontrolled atrial fibrillation digitalis compounds could also be expected beneficially to influence infarct size by reducing the heart rate Finally digitalis compounds can limit the depressant effects of β blockade on the ischemic dog myocardium and thereby actually decrease ischemic injury[76]

Diuretics should act to reduce infarct size in the presence of left sided failure by reducing the preload and hence the heart size

Aminophylline may be used in the presence of bronchospasm associated with left ventricular failure However by inhibition of phosphodiesterase it may increase cardiac cyclic AMP also with an arrhythmogenic effect[2] In critically ill patients there was an inordinately high incidence of cardiac arrest which followed intravenous administration of aminophylline[7,8] Aminophylline is thus probably too suspect to allow its evaluation in relation to infarct size

Morphine has not been studied for effects on infarct size There is some evidence that its effect in pulmonary edema is antiadrenergic[79] in addi

requirement for hemodynamic or metabolic intervention in any given patient could be better assessed

The strongest evidence for the use of anti infarct agents stems from experience with β blockade but even there there is as yet no evidence that reduction of ischemic injury and enzyme release leads to improved long term prognosis

The short history of the therapeutic approach to myocardial infarction has already seen anticoagulants and hypocholesterolemic agents running into strong counterarguments Thus it is prudent to emphasize three major problems

First the hypothesis that a large infarct size is associated with more complications and a higher mortality rate seems acceptable in the light of present evidence [2 34] however the converse hypothesis (therapeutically induced decrease of infarct size fewer complications and lower mortality rate as a result of therapy) still requires proof even though it might seem a self evident truth

Second the data on patients are scanty especially when it comes to effects on indices of infarct size as opposed to indices of ischemic injury

Third until a rapid on line method for the assessment of the development of the infarct process becomes available it will be difficult to select a therapy to meet the specific needs of an individual patient

Conclusions In spite of severe reservations about how best to measure or modify infarct size the concept of modification of infarct size has introduced an entirely new dimension into our management of acute myocardial infarction

Professor A Maseri Fisiologia Clinica Pisa and Charles E Rackley M D kindly provided manuscripts in press I thank Brian M Kennelly M D., and Bernard Gersh M D., for many useful discussions This manuscript forms part of the research program supported in part by the Medical Research Council of South Africa and by the Chris Barnard Fund

Addendum

Since this article was prepared in 1978 two preliminary reports have shown a relation between the use of anti infarct agents and a reduction in mortality in acute myocardial infarction An infusion of nitroprusside for 24 hours followed by isosorbide dinitrate for 7 days reduced death and ventricular fibrillation GIK improved mortality in the randomized trial provided that patients with a low cardiac index or a high pulmonary artery end diastolic pressure were excluded Because both nitrates and GIK appear to have antiarrhythmic properties these studies do not prove a protective effect of limitation of infarct size per se Another study suggests that spasm is not the usual initial event in acute myocardial infarction [261] thereby arguing against relief of spasm as a mode of action of nitrates in acute infarction

inappropriate tachycardia but proof of the efficacy of agents other than practolol is awaited In such patients with heart rates over 100 per minute practolol started within a few hours of the onset of symptoms and then continued has been shown to improve the mortality rate up to one year post infarct but prolonged therapy with practolol can no longer be accepted Some studies[145] and theoretical considerations (Part I of this review) suggest that β blockade could be given to all patients seen early enough and in whom β blockade is not contraindicated provided there is appropriate monitoring in a coronary care unit Furthermore ideal properties of the β blocker (especially in relation to intrinsic sympathetic activity) remain to be determined Whether the possible harmful effects (e g brady cardia hypotension and conduction disturbance) would outweigh the beneficial effects would depend on the success of the monitoring procedures And the possible use of oral β blocking agents other than practolol which is no longer available requires clinical trial Thus further experiments with other β blocking agents is required before definite guidelines can be formulated in such patients

GIK may be an inotropic agent which does not extend infarct size Long acting nitrates are of proven use in selected patients with left ventricular failure complicating acute myocardial infarction but the effects on infarct size are not known Hyaluronidase may come to be the most suitable nonspecific therapy for patients seen in the early hours of the development of the heart attack In every case the results of large scale randomized trials with mortality as end point are awaited and such results will affect the recommendations to be made

Of the agents considered only hyaluronidase and GIK can be given without hemodynamic monitoring in a coronary care unit and GIK requires metabolic monitoring While it would seem ethically acceptable for the agents discussed to be used in individual patients by physicians who understand the problems involved the benefit remains hidden and only the results of large scale randomized trials could uncover the real benefit there might be Until a rapid on line method of measuring an index of infarct size is available assessment of the therapeutic requirements of the individual patient will not be clearly defined

Table X Effect of repetitive intravenous injections of practolol on ST segment elevation (Based on data of Pelides et al [3])

Patient	Times of study (hr post-onset)	Late effect as % of early effect	
		% reduction ST area	% reduction ST elevation
CN	18 and 66 hrs	19%	33%
DW	14 and 38 hrs.	30%	3%
FF	27 and 72 hrs	43%	48%

In summary it must be emphasized that the subject is in the early stages of development The ideal must be to obtain more information on the use of anti infarct agents by rigorously conducted therapeutic trials It would be especially important to obtain studies on the effect of such agents on short and long term mortality rates and for this multicenter trials would be needed In the meantime there are arguments for and against each of the four agents here reviewed

10 What can be hoped for?

Thusfar we have information that two anti infarct measures afterload reduction and hyaluronidase decreased indices of infarct size and that the extent of effect was about 25% in patients judged respectively by creatine kinase curves or Q wave effects Furthermore propranolol decreased creatine kinase release by about 30% [3] Quantification in patients in other cases is not available but a variety of agents decreased measured infarct size by 40% in animals[160] The difference may well be because only patients with a collateral circulation appear to respond to β blockade[31] which could readily be explained by the requirement of a collateral circulation [3, 33] to create a zone of ischemia of lesser severity on which the anti infarct agent should be most active

If the average infarct were to be reduced by only 25% the effect on mortality rate may well not be striking although even a relatively small reduction in infarct size of every individual treated could make a substantial difference in the cumulative mortality rate of a country like the United States of America where acute myocardial infarction is common However the effect on the individual patient will generally not be striking unless new techniques are developed to allow more specific monitoring of the rate at which the infarction process unfolds so that the

Fig 1 The left ventricular outflow tract of a patient with hypertrophic cardiomyopathy is displayed. The anterior mitral valve leaflet has been reflected. Clinically obstruction was present. Severe endocardial thickening below the aortic valve is present together with two systolic (Zahn Schmincke) pockets

Several familial studies have established that hypertrophic cardiomyopathy is a genetically transmitted disease but sporadic occurrence is well recognized

Historical note

Attention to this condition was drawn by Brock in 1957 who illustrated in his report a case of functional obstruction of the left ventricle the patient having been diagnosed clinically as suffering from aortic valve stenosis. At operation the aortic valve was found to be normal and a subaortic muscular bulge of the interventricular septum was noted. The following year the pathology of this condition was detailed. The condition was however recognized in the nineteenth century and Dittrich in 1852 was credited with the first description of this disorder. This credit was misplaced as Dittrich's patient suffered from fibrous subvalvular stenosis. More recently Liouville in 1869 and Hallopeau in 1869 have been credited with the first descriptions of hypertrophic cardiomyopathy. As early as 190[illegible] the disease was called left sided muscular con[illegible] stenosis and a disturbance of embryonic gr[illegible] was suggested as the possible etiologic mecha[illegible]nism

Since the description in 195[illegible] innumerable reports on this condition have appeared in the literature. Great diversity of opinion does ex[illegible] as to whether or not the appearances are pathognomonic or characteristic or whether the changes are non specific merely reflecting severe hypertrophy

The purpose of this review is to critically analyze the various observations that have been reported by numerous workers and to eval[illegible] their findings in order to ascertain whether or not a diagnosis can be achieved pathologically. It is proposed to describe the findings under three major headings macroscopic appearances, microscopic appearances and electron microscopic changes. The description by Teare [illegible] detailed first any subsequent additional obser[illegible]

The pathology of idiopathic hypertrophic subaortic stenosis (hypertrophic cardiomyopathy) A critical review

E G J Olsen M D F R C Path
London England

Idiopathic hypertrophic subaortic stenosis (IHSS) or hypertrophic cardiomyopathy belongs to the group of diseases designated cardiomyopathy a term introduced by Brigden in 1957 Older classifications separated primary forms (where the cause of the heart muscle disease was unknown) and secondary forms (where a disease process elsewhere in the body was associated with cardiovascular manifestations) Much confusion about the classification has arisen since that time and it was suggested that cardiomyopathy should be restricted to those entities in which the cause was unknown (the previous primary group) and that secondary cardiomyopathy should be replaced by the term specific heart muscle disease

Not only has confusion reigned regarding classification but the various types of cardiomyopathy masquerade under several synonyms which for IHSS or hypertrophic cardiomyopathy include functional obstruction of the left ventricle[3] asymmetrical hypertrophy of the heart pseudo aortic stenosis produced by ventricular hypertrophy[5] familial muscular subaortic stenosis obstructive cardiomyopathy simulating aortic stenosis idiopathic hypertrophic subaortic stenosis muscular subaortic stenosis functional subaortic stenosis diffuse subvalvular aortic stenosis[1] muscular subvalvar aortic stenosis hereditary cardiovascular dysplasia hypertrophic subvalvular aortic stenosis[4] subvalvular aortic stenosis of muscular type[5] idiopathic cardiac hypertrophy simulating valvular heart disease[16] hypertrophic obstructive cardiomyopathy[17] primary idiopathic myocardial obstructive hypertrophy[5] hypertrophic cardiomyopathy[9] and hypertrophic cardiomyopathy with or without obstruction[20, 21] Of these many synonyms the terms idiopathic hypertrophic subaortic stenosis and hypertrophic cardiomyopathy have emerged as those most frequently used throughout the world

Despite many suggestions of a possible etiology (or etiologies) no cause for hypertrophic cardiomyopathy has so far been firmly established and therefore this entity belongs by definition to this group of cardiac diseases

The incidence of IHSS is difficult to ascertain in view of the reports having been published from specialized centers Judging from comparative surveys and personal experience it appears that hypertrophic cardiomyopathy occupies an intermediate position in incidence between the other two types of cardiomyopathy the dilated (congestive) type on the one hand and the restrictive/obliterative type which is the rarest form on the other

The earlier British nomenclature (hypertrophic obstructive cardiomyopathy) implied that the obstruction was an essential element of the clinical manifestations Increased clinical experience has however shown that the obstruction is incidental[9] and that the essential hemodynamic abnormality is failure of diastolic compliance

The disease may affect any age varying from the newborn to old age the oldest patient reported being 87 years old[2]

Males are more commonly affected than females in some series[7, 8] but an equal sex incidence has been noted by others[1] In most series the disease is diagnosed in early adult life

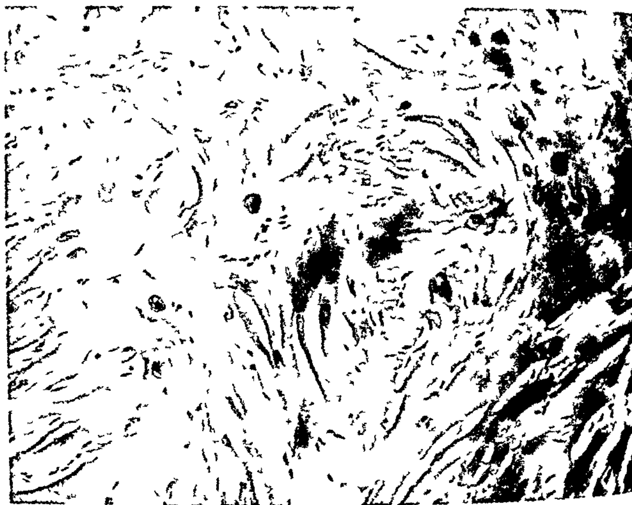

Fig 2 H t r raph f the myocardium from the septal region from a patient firmly diagnosed clinically as affec n h pe phic ardiomyopathy Extensive disarray of myocardial fibers and attempts at whorl m present In addition severe hypertrophy and an increase in collagen tissue interrupting muscle h ll seen Nuclear changes are not prominent Perinuclear halos are absent Although not all diagnostic m e n this illustration the combination of the changes present characterizes this condition H n at lin l eosin stain original magnification ×650)

with congenital heart disease is unreliable This applied particularly to the situation when marked absolute thickening was absent In a clinical and echocardiographic follow up study over a period of two years it has also been shown that resolution of the septal thickening may occur Asymmetric septal thickening can occur in normal embryonic and fetal hearts as well as in the newborn Its association with right ventricular congenital anomalies was stressed Rarely did it accompany abnormalities of left heart development It was therefore suggested that significant asymmetric hypertrophy in the adult heart and in the proper clinical setting can be a valuable diagnostic clue to the presence of hypertrophic cardiomyopathy

Analyzing these various reports there is fairly uniform agreement that minor degrees of asymmetric septal thickening are non specific A severe degree of asymmetric septal thickening in combination with right ventricular congenital anomalies is also not a reliable feature of associated hypertrophic cardiomyopathy Also septal asymmetric hypertrophy even when associated with left sided cardiac anomalies is suggestive of cardiomyopathy In any event great caution must be exercized in interpreting this finding and confirmatory histologic evidence should always be sought

Hypertrophic cardiomyopathy has been noted to occur in a variety of other cardiovascular abnormalities such as lentigenosis congenital abnormalities Turner s syndrome hypertension arterial disease isolated dextroversion and Friedreich s ataxia Unless other evidence exists the presence of asymmetric hypertrophy of the

tions that have been made will then be detailed and each section will be summarized separately in the light of the more recent findings

Macroscopic appearances

Asymmetric hypertrophy of the interventricular septum is striking on naked eye examination and consists of a localized and diffuse hypertrophy of the interventricular septum disproportionate to the rest of the left ventricle The prominent bulge towards the mitral valve was emphasized

The asymmetric hypertrophy of the septum has been consistently confirmed [3n]

Additional descriptive features included simulation of watered silk of the interventricular septum when the ventricles had been transsected[39] Endocardial thickening of the outflow portion of the interventricular septum occasioned by the impact of the anterior mitral valve leaflet the so called mirror image of the leaflet had also been noted A heart showing endocardial thickening is illustrated in Fig 1 Abnormalities of the positioning of the anterior mitral valve leaflet have also been recorded Instead of the normal insertion of the anterior mitral valve leaflet to the base of right aortic valve leaflet in this condition insertion below the posterior aortic valve cusp was noted in two patients Thickening of the mitral valve in cases of mitral insufficiency has been observed in over half the patients In the various descriptions cavity obliteration resulting in a small ventricular cavity has been frequently noted but this is not necessarily always present[47] The normality of the coronary arteries has often been stressed

Measurements of the interventricular septum have indicated that values greater than unity are found when the ratio of the thickness of the interventricular septum and the free left ventricular wall is calculated Echocardiographic identification of asymmetric septal hypertrophy has also been undertaken[1] and a ratio of ventricular septum to posterior left ventricular free wall was 1 03 in normal individuals in patients with fixed left ventricular obstruction and in patients suffering from miscellaneous cardiovascular diseases By contrast in patients with hypertrophic cardiomyopathy the ratio exceeded 1 3 in every case

Asymmetric hypertrophy of the interventricular septum at macroscopic level was therefore considered pathognomonic of hypertrophic cardiomyopathy More recently doubt has been cast on the reliability of this finding when observed alone or in combination with other anomalies of the heart Thus asymmetric septal thickening has been found in normal developing hearts and in association with congenital heart disease and other cardiac conditions[49, 53] In a study of eight cases with asymmetric hypertrophy further histologic examination has shown characteristic features of hypertrophic cardiomyopathy in only two of the eight cases Because of these findings and as a result of another study[50] it was concluded that disproportionate ventricular septal thickening in association with other cardiac diseases may be due to secondary hypertrophy and may not represent genetically transmitted asymmetric hypertrophy

In a study of 125 infants two years of age less interventricular septal to left ventricu free wall thickness ratios of [illegible] or more found in 25% of cases Using ric h trophy as the sole criterion for ing ciated hypertrophic cardiomy m

3 Fibrosis

4 Degenerating muscle with disappearing myofibrils

5 Disorganized whorling muscle

In a longitudinal section the maximum points that could be obtained were 15 This was expressed as 100%

The material had been obtained at surgery where removal of muscle formed part of the operative procedure Comparison with tissue from similar sites also obtained by surgery from patients suffering from tetralogy of Fallot subaortic stenosis ventricular septal defects and mitral valve disease as well as patients with congestive cardiomyopathy was undertaken At the histologic level in just over one half of the patients with hypertrophic cardiomyopathy an index of over 65% was obtained permitting a diagnosis of that condition In the remaining patients overlap between those clinically diagnosed as suffering from hypertrophic cardiomyopathy and the tissue used for comparison existed

Extensive additional *histochemical investigation* had also been undertaken which is summarized in Table I Of the large number of enzymes investigated that of glycogen particularly pooling in the perinuclear areas was helpful in distinguishing hypertrophic cardiomyopathy from hypertrophy of the myocardium due to other causes This finding increased the diagnostic reliability considerably

The morphologic characteristics have not only been confirmed by most workers cited but also by others[44,7]

The specificity of disarray has however been questioned Disarray is found in hearts at the junction of the interventricular septum with the ventricular free walls in congenital heart disease including semilunar valve atresia with intact ventricular septae and tetralogy of Fallot It has also been observed in acquired heart conditions such as systemic hypertension and coronary artery disease Some disarray was also noted in normal hearts but not in the myocardium of developing embryos and fetuses despite disproportionate septal thick[illegible] Irregular arrangement of myocardial fibe[illegible] was also not marked in left ventricular inv[illegible] Therefore neither interventricular se[illegible] [illegible]pertrophy alone nor fiber disarray alo[illegible] the combination of both these features in th[illegible] [illegible] could be considered pathognomon[illegible] [illegible]rtrophic cardiomyopathy[53] In the study of patients with con[illegible] heart disease systemic hypertension cor[illegible] heart disease and patients with cor pulmonal[illegible] disarray of myocardial fibers to a mild degree [illegible] noted in all cases The extent of fiber disar[illegible] individual hearts varied considerably but [illegible] involved less than 11% of the myocardium [illegible] never more than 20% Comparison with a [illegible] with hypertrophic cardiomyopathy showed more than 50% of the myocardium was invol[illegible] not only in the septum but also in the [illegible] walls

A quantitative analysis of disorganized car[illegible] muscle cells in the ventricular septum has [illegible] recently been undertaken[71] In hypertrophic [illegible]diomyopathy septal disorganization was fou[illegible] necropsy in 94% of the 54 patients studied Di[illegible]ganization was extensive in most of th[illegible] patients involving at least five % or more in [illegible] of the sections examined and 25% or more of [illegible] sections in 56% of cases Septal disorganization [illegible] a limited extent was present in only 26% of [illegible] control patients (patients with other heart di[illegible]eases or with normal hearts) In only se[illegible] percent did the abnormally arranged myocard[illegible] fibers occupy five % or more of the tissue sect[illegible] This study has shown that widespread vent[illegible]lar septal disorganization of myocardial fi[illegible] though not pathognomonic of hypertrophied ca[illegible]diomyopathy is a very sensitive and a spec[illegible] histologic marker for this disease

Analyzing the various observations that ha[illegible] been made at the histologic level there is a[illegible] evidence that individual histologic changes ca[illegible] consistently found in hypertrophy other th[illegible] that of hypertrophic cardiomyopathy (see [illegible] example Figs 3c and 4b of reference 53) De[illegible] the unequestionable disarray these ch[illegible] should not in my opinion be interpre[illegible] as representing hypertrophic cardiomyopathy [illegible] Apart from disarray other accompany[illegible] changes such as extreme hypertrophy of fibe[illegible] bizarre nuclei perinuclear halos and increased [illegible] collagen tissue are essential for verification of th[illegible] diagnosis particularly when widely distrib[illegible] the tissue sections The presence of pools of glycogen increases the diagnostic reliability

Electron microscopic changes

Disarray of myocardial fibrils coursing [illegible] verse directions were noted at this level of inv[illegible]tigation[43] (Fig 3) In addition fibrillar degen[illegible]

Fig 3 Electron micrograph showing disarray of myocardial fibrils and widening of Z bands. (Lead citrate and uranyl acetate original magnification ×38 400)

septum cannot be used as a firm diagnostic parameter in these associated conditions

Microscopic appearances

Bizarre arrangement of bundles of myocardial fibers running in diverse directions and separated by connective tissue and clefts were noted The connective tissue was found to interrupt the muscle bundles The thickness of myocardial fibers varied and the clefts were lined by endothelial cells and covered by sparse elastic tissue resembling normal endocardium In some cases these clefts communicated with the cavity of both ventricles but as they pursued a muscle bound course functional shift of blood from one ventricle to the other was considered unlikely

In the original description thickening of the mitral valve was not emphasized Subsequently non specific thickening due to superimposition of collagen tissue on atrial surfaces of the mitral valve leaflets due to mitral insufficiency was observed in approximately half the patients [9]

Disarray of myocardial fibers has been confirmed [1, 21, 38] and was considered to be the most characteristic feature Severe hypertrophy with individual myocardial fibers measuring up to 100 microns in diameter has been observed The presence of clefts has also been reconfirmed not only in the myocardium [4] but also in the conducting system [3] Their significance is not fully understood as they have not been consistently found Their non specificity was emphasized [5, 6]

Other additional fiber alterations have been noted which consist of degenerating myocardial fibrils and the appearance of perinuclear halos as well as a whorled arrangement of myocardial fibers[6] (Fig 2) Changes in the intramural arterioles and small arteries showing medial thickening and cellular intimal proliferation have also been observed [3, 66, 6] These changes were usually mild not resulting in narrowing of the lumen of more than 50% [6]

In an attempt to quantify various histologic parameters an index (the histologic HOCM index) was devised Points from zero to three for each of the following changes were evaluated

1 Short runs of fibers interrupted by connective tissue

2 Large bizarre nuclei

changes is equally reliable If biopsy material permits only one method of analysis that of histology is preferable to ultrastructural or histochemical evaluation It should be remembered that any individual histologic feature is unreliable It is the *combination* of changes that characterize and may indeed be considered pathognomonic of hypertrophic cardiomyopathy

This review has concentrated on the morphologic aspects but it is clear that examination cannot and should not be undertaken without full knowledge of the clinical details Despite the extensive work that has been detailed in this communication there is still further need to define even more precicely the morphologic characterization as well as the clinico pathologic correlation of hypertrophic cardiomyopathy If all these factors are combined the problem as to whether an individual patient does or does not suffer from hypertrophic cardiomyopathy can then be fully solved

tion focal mitochondrial accumulation (the so called mitochondriosis) varying degrees of mito chondrial damage and increased number of lyso somes and lipofuchsin granules together with swelling of the sarcotubular system were noted Comparison with tissue obtained from cases with other conditions resulting in hypertrophy was also made Analysis of seven electron microscop ic features showed that extensive overlap between those patients with hypertrophic cardiomyopa thy and the control cases existed

By contrast other workers considered disar ray of myocardial fibrils which did not occur necessarily in all cells together with abnormally arranged myofilaments abnormal intercellular junctions and abnormalities of Z bands as con stituting distinctive changes Minor abnormali ties of myofibrillar disorganization were however noted in three out of 31 patients with congestive cardiomyopathy [73] Disorganization of myofibrils and other abnormal features have been widely confirmed [74-77]

Overlap between hypertrophic cardiomyopathy and other conditions resulting in hypertrophy of the myocardium[6] has been confirmed by oth ers [4, 8, 79] Indeed it has been suggested that intracellular disarray was more frequent in acquired heart disease than in hypertrophic car diomyopathy Irregular arranged myocardial fibrils have also been observed in the zones adja cent to experimental myocardial infarction[5, 8] and in embryonic heart muscle [8]

Analyzing the reports on electron microscopic findings *it has become clear that the features of* hypertrophic cardiomyopathy can be extensively mimicked by other cardiac conditions which result in hypertrophy If however intra and interfibrillar disarray is extensive the changes are suggestive but not pathognomonic of hypertro phic cardiomyopathy

So far distinction between two clinical groups recognized for several years has not been made In one group obstruction of the outflow of blood from the left ventricle (or right or both ventricles) played a significant role in the clinical symptoma tology In the other group of patients obstruction has never been clinically manifest Macroscopic studies have shown non uniform distribution of free wall thickening but a normal posterobasal region in non obstructive cases whereas in patients with obstruction uniform thickening of the entire left ventricular free wall was found including the posterobasal part [31, 83] Asymmetric hypertrophy of the ventricular septum was more pronounced in that group In another study absence of asymmetric hypertrophy of the inter ventricular septum was considered indicative of non obstruction during life In those cases where asymmetry of the interventricular septum was present obstruction or non obstruction may have existed [8] Absence of asymmetric hypertrophy of the septum did not deny a diagnosis of hypertro-phic cardiomyopathy [78] and dilatation of the ven tricular cavities prior to death may occur [9]

Histologic histochemical and ultrastructural changes are similar to those that have already been noted but the distribution of abnormal myocardial fibers is different in the two clinical groups In hypertrophic cardiomyopathy with obstruction the abnormal myocardial fibers and fibrils are mostly confined to the asymmetrically hypertrophied interventricular septum In cases without obstruction the fibers are distributed focally through left and or right ventricular walls including the septum [70, 84-86] These differences of distribution have been considered to account for the differences in clinical manifestations Caution of interpreting these findings was however sounded Such caution was well placed because other morphologic studies have shown wide spread involvement of left ventricular walls in cases of patients with obstruction [35] Two children with clinical evidence of obstruction have recent ly been described who showed at postmortem the characteristic distribution of non obstruc tion [87]

These studies on the different distribution of abnormal fibers and fibrils in the obstructive and non obstructive groups have shown that morpho logic criteria are not altogether reliable in relation to clinical findings The cases so far reported are relatively few and therefore further work must be undertaken to evaluate more fully these differ ences

It may finally be concluded that despite the various observations and sometimes contradicto ry interpretations of the morphologic findings at macroscopic microscopic and ultrastructural level one clear pattern has emerged When suffi cient material is available suitable for histologic histochemical and ultrastructural examination the combination of these methods permits diag nosis with a high degree of accuracy Examina tion at necropsy of macroscopic and histologic

DR ROBERTS Herein we will discuss a child with congenital heart disease and trisomy 13 Dr Cabin will present the patient s clinical and morphologic findings

DR CABIN J M (CC No 13 31 03) was a 4 5 month old girl who died on July 10 1979 She weighed 2 4 kilograms at birth after a 37 week gestation A precordial murmur was noted during the first 2 weeks of life and she was acyanotic At age 15 days she was transferred to the Clinical Center of the National Institutes of Health because of feeding difficulties and intermittent signs of congestive heart failure Her blood pressure was 70/40 mm Hg her heart rate was 172 beats/minute and the respiratory rate was 80 breaths/minute Her head was small (microcephaly) both eyes were small (microphthalmia) and a fissure was present in the left iris (coloboma) She had a cleft upper lip and palate a preauricular skin tag transpalmar (Simian) creases partial fusion (frog like) of her toes (syndactylism) and a rudimentary extra digit (polydactyly) on her left hand and left foot The right ventricular impulse was palpable S was single and loud and a Grade 3/6 systolic ejection type murmur was heard along the upper sternal border The lungs were clear The chest radiograph (Fig 1) disclosed

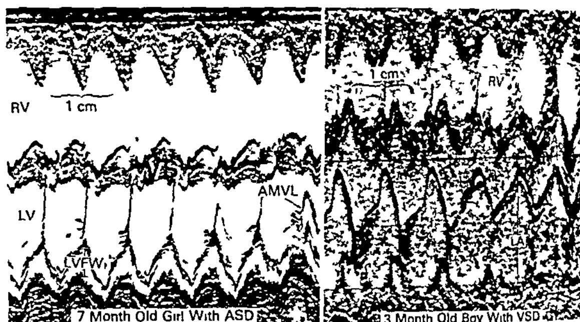

Fig 3 Echocardiograms from two patients *Left* A 7 month old girl with a secundum type atrial septal defect *(ASD)* The right ventricle *(RV)* is dilated and the ventricular septum *(VS)* moves paradoxically during ventricular systole The left ventricle *(LV)* is of normal size *LVFW* = left ventricular free wall *AMVL* = anterior mitral valve leaflet *Right* Echocardiogram from a 3 month old boy with a ventricular septal defect *(VSD)* The left atrium *(LA)* is dilated and the aorta *(Ao)* is of normal size consequently the LA to Ao ratio is increased.

cally The aorta was mildly enlarged and the left atrial to aortic ratio was normal (1 0 [normal range = 0 8 to 1 2]) These findings are of considerable help in sorting out the level of a left to right shunt Both VSD and PDA result in dilated left atria and left ventricles,[3 5] because of volume overload of the left sided chambers from the left to right shunt The right ventricle may enlarge to some extent the right atrium does not dilate An ASD causes right atrial and right ventricular volume overload without left sided enlargement This right sided overload may result in paradoxical movement of the ventricular septum during ventricular systole[6 8] Thus M mode echocardiograms in infants with VSD (Fig 3) or PDA show increased left ventricular and left atrial dimensions with increased left atrial to aortic root ratios ASD produces an increased right ventricular dimension the left ventricular and left atrial dimension are normal or smaller than normal and the left atrial to aortic root ratios are normal (Fig 3)

In our infant all three chambers seen by the M mode echocardiogram were normal in size and therefore the presence of ASD VSD or PDA as an isolated defect was most unlikely The combination however of an ASD with a PDA and/or a VSD could result in a normal sized left atrium particularly if the atrial shunt were large

The left or right ventricle could be normal or increased in size depending upon the rel[illegible] magnitude of each shunt Thus the M[illegible] echocardiogram in combination with the o[illegible] findings in our patient suggested the diagnos[illegible] ASD in combination with VSD and/or PDA

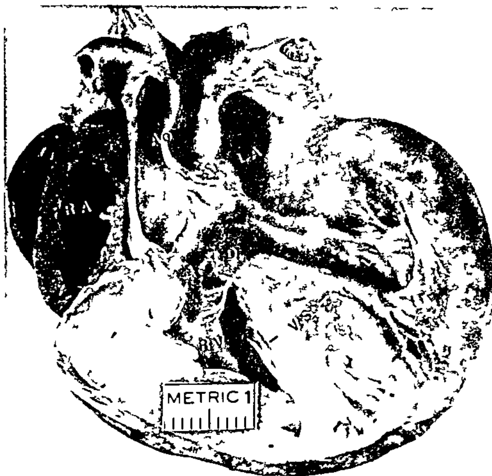

Fig 2 Longitudinal section of the heart The walls of both the right *(RV)* and left *(LV)* ventricles are hypertrophied a defect *(D)* is present in the most cephalad portion of the ventricular septum *(VS)* the right atrium *(RA)* is large and the aorta *(Ao)* and left atrium *(LA)* are of normal size (Photo by M M M Moore)

patients reported by Warkany and associates congenital heart disease occurred in 27 (84%) of 32 necropsy patients with trisomy 13 in 83 (99%) of 84 patients with trisomy 18 and in 141 (52%) of 272 patients with trisomy 21 The most commonly found malformations in trisomy 13 were VSD PDA and ASD and two or three of these three defects occurred more frequently than a single defect These three defects also were common in patients with trisomy 18 and 21 The most common type of atrial septal defect in trisomy 21 is one located in the lowermost portion of the atrial septum (ostium primum or endocardial cushion type) and in trisomy 13 and 18 the defect most commonly is in the mid portion of the atrial septum (secundum type)

The occurrence in our patient of signs of congestive heart failure acyanosis and enlarged right sided cardiac chambers with evidences of increased pulmonary blood flow strongly suggested the presence of a left to right shunt at the atrial ventricular or great artery level or combinations of these three The presence of trisomy 13 strongly suggested the presence of two or more of these defects

Dr Roberts The echocardiogram has proved useful in delineating the level of a left to right shunt Dr Lester has recently analyzed the usefulness of echocardiography for characterization and quantitation of a left to right shunt in patients with ventricular septal defect [2] Dr Lester can you summarize the echocardiographic findings in patient J M and from your previously collected data how useful is the echocardiogram in predicting the level of the shunt in patients with left to right shunts?

Dr Lester An echocardiogram was performed at 15 days of life (Fig 1) The left and right ventricles and left atrium were normal in size The ventricular septum did not move paradoxi

disease causes a granular cobblestone appearance with nodular filling defects corresponding to the exudative plaques seen endoscopically The most common viral cause of esophagitis is herpes simplex, which tends to cause focal ulcers but may produce filling defects similar to moderate monilial disease

Further investigation of the symptom of heartburn is indicated if the patient does not respond to therapy if there is a complication of the peptic esophagitis (such as stricture or ulceration) or if the diagnosis of esophagitis or gastroesophageal reflux is still in doubt Esophageal manometry demonstrates a reduced lower esophageal sphincter pressure in 80 to 100% of patients with severe reflux esophagitis[10] A normal lower esophageal sphincter pressure suggests that reflux esophagitis is not the etiology of the patient s pain In situations of continued suspicion of peptic esophagitis but equivocal manometric findings direct demonstration of acid reflux is helpful[11 1] Acid reflux may be demonstrated by placing a pH probe in the distal esophagus and instilling 0 1 N hydrochloric acid into the stomach A fall in esophageal pH below 4 suggests the presence of reflux This test has a greater than 90% yield in patients with reflux and very few false positive or false negative responses A more recent method to demonstrate reflux is the use of a radioisotopic marker ingested with an exogenous fluid load[13] Reflux of the isotope detected by gamma camera is an accurate and sensitive method but is not yet widely available

If studies have demonstrated gastroesophageal reflux but there remains a question whether the patient has esophagitis three other tests may be performed the Bernstein Test esophagoscopy and esophageal biopsy[1] The Bernstein Test is a provocative test which reproduces the classic pain of reflux esophagitis by perfusion of the esophagus with 0 1 N hydrochloric acid The acid is perfused in a blinded fashion alternating with saline Saline will relieve the discomfort by washing acid from the esophagus False positive responses are unusual and about 90 c of patients have a positive response

Esophagoscopy is helpful when it is not clear whether the patient s reflux is complicated by peptic esophagitis or when there is a complication of the peptic esophagitis such as stricture or ulceration which requires biopsy to exclude malignancy Esophagoscopy permits biopsy or cytologic examination to detect other causes of esophagitis, such as fungal or viral However the [illegible] bits of tissue obtained through the flexible [illegible] agoscope are often not adequate for [illegible] identification of reflux esophagitis Visual [illegible] ment via the esophagoscope may be falsely [illegible] tive or positive when the changes are [illegible] Biopsy of the distal esophagus by a [illegible] capsule under fluoroscopic guidance prov[illegible] accurate histologic identification of esophag[illegible] Less than 10% of normal controls will [illegible] evidence of esophagitis on such a biopsy where[illegible] approximately 90% of patients will have typ[illegible] features

Odynophagia or pain on swallowing [illegible] ond common cause of chest pain caused [illegible] esophageal disease Depending upon the und[illegible] lying etiology of the odynophagia this sym[illegible] may be precipitated by swallowing solids or [illegible] uids When the pain is the result of a m[illegible] disorder of the esophagus both solids and liqu[illegible] especially if very hot or very cold may [illegible] symptoms With obstructive lesions of the [illegible] phagus such as carcinoma or stricture od[illegible] phagia is brought on more commonly by swall[illegible] ing solid food Irritant liquids such as fruit ju[illegible] coffee or spicy drinks may cause odynophagia [illegible] there is esophagitis[18] A barium swallow is th[illegible] most important test to perform in a patient [illegible] odynophagia This test will usually demonstra[illegible] structural abnormalities such as carcinomas [illegible] strictures and occasionally the mucosal irre[illegible] larities of esophagitis or moniliasis or a m[illegible] disorder Although chest pain is a major c[illegible] plaint in only 25% of patients with achalasia [illegible] barium swallow will be abnormal in all T[illegible] characteristic findings are smooth tapering of th[illegible] distal esophagus and nonperistaltic tertiary c[illegible] tractions Diffuse esophageal spasm howev[illegible] may not show abnormalities on conventi[illegible] barium swallow in spite of chest pain

Cine radiography improves the diagnostic [illegible] curacy of the barium study when a motor d[illegible] der is present Abnormalities in mucosa produ[illegible] odynophagia will be recognized with a vari[illegible] success on barium swallow[1] If the study [illegible] good quality especially with air contrast [illegible] ing carcinomas will be easily detected The p[illegible] bility however of missing an early carcino[illegible] the esophagus as well as difficulty in de[illegible] peptic or infectious esophagiti[illegible] make [illegible] scopy an important diagnostic tool in the [illegible] tion of odynophagia

If the barium swallow suggests a motor d[illegible]

The digestive tract as a cause of chest pain

William B Long M D
Sidney Cohen M D
Philadelphia Pa

Disease of the digestive tract may cause chest pain and be the chief complaint in a patient presenting to a cardiologist A relationship of symptoms to the digestive functions of eating or defecation suggests gastrointestinal etiology The autonomic nerve supply of the esophagus is similar to that of the heart and pain from this organ often closely mimics cardiac pain Of patients referred for gastrointestinal investigation because of angina like pain but no other evidence of coronary artery disease about half are found to have an esophageal etiology for the pain Disorders of the stomach duodenum and biliary tree and less commonly colonic pancreatic hepatic or peritoneal disease can cause upper abdominal or chest pain The problem may be either a functional motility disorder or a structural pathologic entity The diagnositc problem is compounded when digestive disease and cardiac disease coexist Occasionally provocative tests designed to elicit pain from the digestive tract give assistance but frequently one must rely upon a clinical distinction

Chest pain of esophageal origin

The three major types of chest pain of esophageal origin are heartburn odynophagia (pain on swallowing) and spontaneous esophageal spasm Heartburn is characterized by retrosternal burning sensation which travels up from the xyphoid and is made worse by certain foods and by recumbency[3] In about 40% of patients pain radiates to the back and in 5% it radiates to the arms or neck[1] Heartburn is seen in increased frequency in patients with scleroderma following resection of the lower esophageal sphincter during pregnancy and during medication with certain drugs especially anticholinergics When heartburn is severe enough to be a major complaint the patient should have a barium swallow which will reveal the major complications of gastroesophageal reflux stricture and peptic ulcer of the esophagus Barium swallow demonstrates gastroesophageal reflux in 10 to 25% of patients[5] The finding of reflux may be increased to about 50% by the use of cine esophagography The water siphon test (in which a water swallow relaxes the lower esophageal sphincter) or an acid barium swallow are designed to demonstrate reflux more frequently or initiate disordered esophageal motility if esophagitis is present however both of these tests have a high false positive response which limits their usefulness[6] The presence of hiatal hernia on barium swallow has been found to correlate poorly with gastroesophageal reflux and is therefore not a significant aid to the clinician[8, 9] Functional integrity of the lower esophageal sphincter which prevents reflux of acid from the stomach into the esophagus and esophageal peristalsis which clears acid from the esophagus are the significant determinants of peptic esophagitis

Studies of the esophagus by barium swallow deserve special mention not only because they are the first studies needed in evaluating suspected esophageal disease but also because of recent improvements in technique[4] The most notable improvement in technique is the use of air contrast The earliest manifestations of esophagitis recognized with confidence are superficial erosions or ulcers Occasionally edema of the subtle transverse esophageal folds is noted Local areas of eccentric decreased distensibility or finely nodular mucosa are chronic changes Monilial esophagitis the most common infectious esophageal

this therapy as would be expected or if there are atypical features which suggest esophagitis of other etiologies then esophagoscopy often with biopsy or cytologic brushings is indicated If the barium swallow and esophageal manometry are typical of diffuse esophageal spasm and the Bernstein Test does not reproduce the patient's pain the patient may be treated with anticholinergics or nitrites without further investigation

Other organic disease

Although structural disease of the remainder of the gastrointestinal tract biliary tree pancreas liver, or peritoneal cavity may produce pain in the upper abdomen or lower chest these disorders often have features which distinguish them clinically from cardiac pain and they may be readily diagnosed if they are considered Ulcers within the stomach or duodenum occasionally cause lower chest pain, but the typical burning pain with relief following meals or antacids mandates the performance of an upper gastrointestinal x ray Occasionally a patient will have a superficial ulcer or gastritis in a normal stomach or an ulcer in an area difficult to evaluate radiographically (for instance an ulcer in a patient with a Bilroth II operation) and endoscopy reveals the pathology Biliary colic may cause pain in the high epigastrium and occurs within a few hours following a meal but may also be spontaneous Biliary colic is a misnomer since the pain is usually constant and lasts for one half hour to several hours The pain is often associated with nausea and vomiting and may radiate into the right scapula or right upper quadrant Acute cholecystitis may also cause high epigastric discomfort but is more likely to be associated with right upper quadrant pain and tenderness This pain is of longer duration than the pain of biliary colic and is associated with signs of inflammation such as leukocytosis or fever An oral cholecystogram or ultrasound of the gallbladder are reliable tests in over 95% of patients for the detection of gallstones Ultrasound is especially useful in the jaundiced patient Acute cholecystitis may be ruled out by gallbladder visualization on oral cholecystogram or gamma camera scanning following injection of one of the newer radionucleotides excreted in the bile

Acute pancreatitis pain radiates through into the back is persistent and usually is associated with an elevated serum amylase or urinary amylase clearance The pain of chronic pancreatitis is also persistent and penetrating to the back from the epigastric area with exacerbation following meals or drinking of alcohol Pseudocysts of the pancreas are notorious for their ability to present in unusual locations Dissection of a pseudocyst into the mediastinum may cause chest pain and dysphagia Chronic pseudocysts have been reported to have normal serum amylase in up to 50% of patients Occasionally pseudocysts may erode into the pleural space causing a pancreatic pleural fistula and generate chronic chest pain A chest x ray will show a pleural effusion especially on the left Endoscopic retrograde pancreatography is of value in diagnosing chronic pancreatic disease (small cysts chronic pancreatic fistula or carcinoma) and in assisting the surgeon in planning appropriate operative intervention Abdominal ultrasound or computerized tomography are other valuable noninvasive tests which detect pancreatic hepatic or subphrenic disease[3]

Functional gastrointestinal disorders causing chest pain

Motility disorders of the intestinal tract [illegible] biliary tree are more difficult to identify than [illegible] the structural disorders mentioned above Irritable bowel syndrome is now widely accepted as [illegible] distinct disorder which can be identified by specialized motility studies Recent investiga[illegible] have revealed that muscles of the large intestine in these patients have an abnormal myoelectric activity in the resting state with a predominant [illegible] of three cycle per minute activity in contrast [illegible] the normal predominance of six cycles per minute[31] These patients also show abnormal [illegible] prandial colonic spike potentials and co[illegible] tions[3] Normal individuals respond to a [illegible] containing fat by rapid increase in colonic [illegible] tractions which subside over an hour and a [illegible] Patients with irritable intestine on the o[illegible] hand demonstrate a delayed increase in [illegible] activity which peaks at a time when the [illegible] activity is decreasing Colonic motility stu[illegible] performed only in a few centers and under [illegible] circumstances we must rely upon exclu[illegible] structural disease and typical symptomat[illegible] Patients with irritable intestine character[illegible] are young adults with a chronic history of [illegible] abdominal pain exacerbated by meals The[illegible] experience diarrhea or constipation or both [illegible]

able I Diagnostic procedures to evaluate gastrointestinal causes of pain

Organ	*Suspected disorder*	*Primary tests*	*Secondary tests*
sophagus	Esophagitis	Barium swallow Esophageal manometery Esophagoscopy and biopsy Bernstein Test	pH probe Reflux scan
	Obstructive lesion	Barium swallow Esophagoscopy and biopsy	
	Motor disorder	Barium swallow Esophageal manometry Esophagoscopy	Cine-esophagogram Bernstein Test
tomach and intestine	Ulcer	Upper gastrointestinal series duodenoscopy	
	Irritable bowel	Barium enema Proctoscopy	Colonic motility studies
iliary tree	Gallstones	Oral cholecystogram Abdominal ultrasound	IV cholangiogram Biliary scan
	Dyskinesia	ERCP ? Sphincter of Oddi manometry	? Morphine test
ancreas	Acute or chronic disease	Serum amylase Abdominal echo or CAT ERCP	

ler of the esophagus esophageal manometry will give significant clinical information In achalasia peristalsis is absent and may be replaced by nonperistaltic (tertiary) waves The pressure of the lower esophageal sphincter is elevated and undergoes incomplete relaxation on swallowing

In diffuse esophageal spasm there are tertiary contractions of the esophagus but some peristaltic activity is preserved The tone of the lower esophageal sphincter may be normal or in some cases elevated and may simulate that seen in achalasia[2] Swallows of hot or cold liquids may precipitate tertiary contractions in these patients

Esophagoscopy is indicated in patients with achalasia not only because of the long term risk of carcinoma superimposed upon achalasia but because of the ability of carcinoma of the distal esophagus or adjacent structures which has invaded the esophageal nerves to mimic achalasia Patients in whom carcinoma is producing a idiographic and manometric picture identical to chalasia tend to be older to have symptoms for several months only and to have weight loss in xcess of that expected from the duration of their sophageal symptoms

The third type of chest pain of esophageal rigin is spontaneous chest pain caused by diffuse sophageal spasm The pain of spontaneous diffuse esophageal spasm is similar to the crushing substernal chest pain induced by eating in patients with odynophagia [1] Spontaneous esophageal chest pain is usually caused by an esophageal motor disorder It occasionally is a manifestation of carcinoma or esophagitis When the spontaneous esophageal spasms are the result of esophagitis appropriate therapy of the esophagitis may relieve the spasm and pain Patients whose esophageal spasm is a manifestation of a primary motor disorder may obtain relief by the use of nitroglycerin Symptomatic relief of esophageal pain by sublingual nitroglycerin simulates the response seen in cardiac pain Esophageal discomfort however is not brought on by exertion or relieved by rest Often the patients with spontaneous esophageal chest pain and spasm will have odynophagia or dysphagia The initial diagnostic test is a barium swallow as in the case of patients with heartburn or odynophagia Because these patients are most likely to *have a motor disorder especially diffuse esophageal spasm* esophageal manometry is usually the next procedure performed At the time of esophageal manometry it is often valuable to perform a Bernstein Test to reproduce the patient s symptoms if they are secondary to esophagitis If the barium swallow shows reflux from the stomach the Bernstein Test is positive and the lower esophageal sphincter pressure is reduced it is reasonable to treat such patients with antacids or cimetidine [3] If the patient does not respond

notice mucus on the bowel movement Most patients have lower abdominal crampy pain but patients with the so called splenic flexure syndrome have left upper quadrant pain which may radiate to the shoulder In order to establish a diagnosis of irritable intestine one must first exclude other diseases with a normal upper intestinal x ray and barium enema In addition most clinicians insist upon a normal proctoscopic examination and no evidence of inflammation on white blood count or erythrocyte sedimentation rate The pain and bowel irregularities of these patients may respond to low fat high fiber diet and to anticholinergic therapy

Biliary dyskinesia is a poorly documented phenomenon for which there is beginning to emerge objective evidence The pain of these patients mimics biliary colic but gallstones or structural abnormality are not found[7] If the gallbladder is present it empties poorly in response to intravenous cholecystokinin infusion or fatty meal and the characteristic pain is reproduced Some investigators have noted the gallbladder to distend as if straining to empty against a resistance There is controversy regarding the significance of these findings and surgical therapy must be undertaken with great caution Poor gallbladder emptying is also seen in diabetic and post vagotomy patients but does not cause symptoms

Another group of patients with suspected biliary dyskinesia are those who have previously undergone a cholecystectomy but present with similar biliary symptoms[7] Good visualization of the bile duct is essential to document the absence of organic disease Intravenous cholangiography has a high false negative rate and retrograde transhepatic or operative cholangiography is needed[3] Recent and as yet unconfirmed evidence suggests that these patients have an elevated sphincter of Oddi pressure determined during endoscopic retrograde cannulation The bile duct may be slightly dilated and the radiographic dye may drain slowly Others have advocated the use of a morphine and cholinergic stimulation test which reproduces the patient s pain and causes elevated serum amylase lipase or liver enzymes[4] The value of this provocative test has been questioned by findings that normal volunteers may also have an increase in these enzymes or experience pain following morphine and cholinergic stimulation Although it remains difficult to obtain objective evidence of post cholecystectomy biliary dyskinesia some centers have reported beneficial effects of sphincteroplasty especially when the septum between the bile duct and pancreatic duct is divided Long follow up of patients chosen for sphincteroplasty because of abnormal sphincter pressure is not yet available Sphincteroplasty is difficult has significant morbidity and must be undertaken only following the most careful clinical assessment When surgery is performed on the bile duct the surgeon may describe a thickened septum between a common bile duct and the pancreatic duct Medical therapies which have been tried in these patients include anticholinergics long acting nitrites and low fat diets As is the case with gallstone patients most of the patients are female and they often have had symptoms for a prolonged period prior to cholecystectomy

In summary various gastrointestinal disorders may cause chest pain In most cases a distinction between these disorders and cardiac disease can be made by history The most difficult condition to distinguish from cardiac disease is symptomatic diffuse esophageal spasm but history barium swallow and especially esophageal manometry have now allowed an easier distinction to be made

reach or decrease below the 95th percentile of the age group of the patient we proceed with drug treatment Our mean values for plasma cholesterol levels and the 95th percentile cutting points are given in Table I Our 95th percentile for plasma triglycerides is 200 mg %

The drugs presently available on the market are few in number have limited efficacy, and may have multiple side effects Instead of being complete or exhaustive I shall restrict myself to the description of those drugs that are the most effective or the most widely used for the treatment of hyperlipidemia

Clofibrate (CPIB) Ethyl p chlorophenoxysobutyrate (CPIB) is a branched chain fatty acid ester

Indications Clofibrate is the drug of choice in the treatment of hypertriglyceridemia Many patients with combined hyperlipidemia also respond

Effect Clofibrate reduces plasma triglyceride levels by about 30% to 40% and plasma cholesterol levels by 5% to 15% In hypertriglyceridemic patients LDL and HDL concentrations increase and VLDL decreases The response in hypercholesterolemia is poor

Mechanism of action Sterol balance measurements indicated a significant increase of the fecal excretion of cholesterol end products (neutral sterols)[5] and a decrease of cholesterol absorption[6] during clofibrate administration inducing a negative sterol balance (more cholesterol end products coming out than cholesterol going in) The action on triglycerides seems to be both a decrease of VLDL production and acceleration of its catabolism to LDL Or simply endogenous triglycerides are synthesized slower by the liver and once made they are broken down faster

Side effects Nausea and diarrhea may rarely occur We have seen a few cases of myalgia with elevated CPK levels returning to normal after cessation of drug administration It has been shown that the drug produces lithogenic bile and both the CDI and the WHO study[2] demonstrated increased rates of cholelithiasis and diseases of the biliary tract in patients receiving clofibrate

Drug interact[illegible] Clofibrate increases the effect of coum[illegible] anticoagulants Patients should be carefull[illegible] monitored on both medications

Dose and costs Dose is 500 mg capsules four times daily (or two capsules twice a d[illegible] January 1980 the cost *to our pharmac[illegible]* was [illegible] per 100 capsules

Cholestyramine and colestipol [illegible] unabsorbable high molecular weight [illegible] exchange resins

Indications The drug of choice in hyperch[illegible]terolemia and the drug to be used in ch[illegible] when drug treatment is indicated

Effect These compounds reduce plasma ch[illegible]terol levels by about 20% to 30% Plasma trig[illegible]erides may moderately increase during [illegible] administration LDL cholesterol is decrea[illegible] VLDL triglycerides may moderately incr[illegible] and HDL remains unchanged[7,8]

Mechanism of action Cholestyramine [illegible] colestipol bind bile acids in the gastrointe[illegible] tract, thereby interrupting the enterohepatic c[illegible]culation Bile acids are an important end pro[illegible] of cholesterol metabolism and their incre[illegible] fecal excretion leads to a more rapid convers[illegible] cholesterol to bile acids which significa[illegible] decreases the plasma cholesterol concentra[illegible] Cholesterol absorption is somewhat decrea[illegible] but only if the drug is taken *before* meals[9]

Side effects Constipation is the most freque[illegible]ly seen complication sometimes improved [illegible] the use of stool softeners The taste and con[illegible]tency of the resins which are not soluble in w[illegible] may also be unpleasant

Drug interactions It may reduce the abs[illegible]tion of a number of compounds (digitalis [illegible] soluble vitamins iron thyroid preparat[illegible] tetracycline thiazides etc) It is recomme[illegible] that any other medication be taken at leas[illegible] hour before the resins

Dose and costs Begin with one 4 gm sa[illegible] *before* each meal (three times daily) and th[illegible] may be doubled or even tripled in adults [illegible] January 1980 the cost *to our pharmac[illegible]* [illegible] $48 18 per 100 sachets

Nicotinic acid This is a vitamin of the B g[illegible] (niacin) which prevents pellagra given in [illegible] larger doses to reduce plasma lipids

Indications Nicotinic acid is the only [illegible]lowering drug which is highly effective in red[illegible] both plasma cholesterol and triglyceride lev[illegible] is indicated in hypercholesterolemia hyper[illegible]glyceridemia and combined hyperlipidem[illegible] [illegible]sibly in combination with other drugs (see Ta[illegible] III)

Effect Nicotinic acid lowers plasma chole[illegible]

rug treatment of hyperlıpıdemıa

ɜul Samuel M D
-w York N Y

'urıng the past decade we have wıtnessed one of ıe major controversıes of modern pharmacology ı the field of drugs used for the treatment of yperlıpıdemıa First as ıs frequently the case ıe lapse of tıme ımproved methodology and the dvent of large clınıcal trıals have demonstrated gnıficant and hıtherto unsuspected sıde effects f a number of drugs wıdely used ın the field lofibrate was shown to ınduce gallstone forma ıon[1,2] d thyroxın caused sıgnıficant cardıac rrhythmıas[3] estrogens ıncreased thromboem olıc complıcatıons[3] just to mentıon a few Sec nd the valıdıty of drug ınterventıon ıtself has ecome the subject of controversy and has been erıously questıoned The results of the Coronary Drug Project and of the World Health Organıza ıon trıal[?] showıng no dıfference ın cardıovascular nortalıty rate between patıents ın the control and drug treatment groups have raısed concerns ıbout the valıdıty and efficacy of drug treatment n thıs field

Justıfiably the questıon has to be asked what re we treatıng numbers or people?

And yet despıte the controversy we are faced vıth more and more evıdence whıch ındıcates hat ıncreased plasma lıpıd levels are a sıgnıficant ıealth hazard and ought to be reduced by what ver means The epıdemıologıc evıdence ıs over vhelmıng ındıcatıng ıncreased rısk of cardıovas 'ular dısease as plasma lıpıds go up Concernıng he clınıcal trıals the reductıon of plasma choles erol levels ın the CDP was only 6% wıth clofibrate one would really not expect too much of that Conversely ın the WHO study there was a sıgnıficant reductıon ın the ıncıdence of nonfatal myocardıal ınfarctıon yet thıs result was obtaıned wıth only a 9% reductıon of serum cholesterol levels (Sımılar results were seen wıth nıcotınıc acıd ın the CDP) Moreover ın the WHO study the reductıon of myocardıal ınfarc tıon ın the clofibrate treated group was most marked ın men who experıenced the largest reductıons ın plasma cholesterol levels Thus the results of the WHO study offer the first clear cut support for the lıpıd hypothesıs whıch postu lates that reducıng plasma cholesterol by what ever means should lead to a lower ıncıdence of cardıovascular morbıdıty and mortalıty

Table I Average plasma cholesterol concentra tıons and 95th percentıles accordıng to age

reach or decrease below the 95th percentile of the age group of the patient we proceed with drug treatment Our mean values for plasma cholesterol levels and the 95th percentile cutting points are given in Table I Our 95th percentile for plasma triglycerides is 200 mg %

The drugs presently available on the market are few in number, have limited efficacy, and may have multiple side effects Instead of being complete or exhaustive, I shall restrict myself to the description of those drugs that are the most effective or the most widely used for the treatment of hyperlipidemia

Clofibrate (CPIB) Ethyl p chlorophenoxysobutyrate (CPIB) is a branched chain fatty acid ester

Indications Clofibrate is the drug of choice in the treatment of hypertriglyceridemia Many patients with combined hyperlipidemia also respond

Effect Clofibrate reduces plasma triglyceride levels by about 30% to 40% and plasma cholesterol levels by 5% to 15% In hypertriglyceridemic patients LDL and HDL concentrations increase and VLDL decreases[4] The response in hypercholesterolemia is poor

Mechanism of action Sterol balance measurements indicated a significant increase of the fecal excretion of cholesterol end products (neutral sterols)[5] and a decrease of cholesterol absorption[6] during clofibrate administration inducing a negative sterol balance (more cholesterol end products coming out than cholesterol going in) The action on triglycerides seems to be both a decrease of VLDL production and acceleration of its catabolism to LDL Or simply endogenous triglycerides are synthesized slower by the liver and once made they are broken down faster

Side effects Nausea and diarrhea may rarely occur We have seen a few cases of myalgia with elevated CPK levels returning to normal after cessation of drug administration It has been shown that the drug produces lithogenic bile and both the CDP[1] and the WHO study[2] demonstrated increased rates of cholelithiasis and diseases of the biliary tract in patients receiving clofibrate

Drug interactions Clofibrate increases the effect of coumarin anticoagulants Patients should be carefully monitored on both medications

Dose and costs Dose is 500 mg capsules four times daily (or two capsules twice a da[illegible] January 1980 the cost *to our pharmacy* [illegible] per 100 capsules

Cholestyramine and colestipol [illegible] unabsorbable high molecular weight [illegible] exchange resins

Indications The drug of choice in hyper[illegible] terolemia and the drug to be used in ch[illegible] when drug treatment is indicated

Effect These compounds reduce plasma ch[illegible] terol levels by about 20% to 30% Plasma tri[illegible] erides may moderately increase during [illegible] administration LDL cholesterol is decrea[illegible] VLDL triglycerides may moderately incre[illegible] and HDL remains unchanged[7,8]

Mechanism of action Cholestyramine [illegible] colestipol bind bile acids in the gastrointest[illegible] tract thereby interrupting the enterohepatic c[illegible] culation Bile acids are an important end pro[illegible] of cholesterol metabolism and their incre[illegible] fecal excretion leads to a more rapid conver[illegible] cholesterol to bile acids which significa[illegible] decreases the plasma cholesterol concentra[illegible] Cholesterol absorption is somewhat decrea[illegible] but only if the drug is taken *before* meals[4]

Side effects Constipation is the most frequ[illegible] ly seen complication sometimes improved [illegible] the use of stool softeners The taste and con[illegible] tency of the resins which are not soluble in wa[illegible] may also be unpleasant

Drug interactions It may reduce the ab[illegible] tion of a number of compounds (digitalis [illegible] soluble vitamins iron thyroid preparatio[illegible] tetracycline thiazides etc) It is recommen[illegible] that any other medication be taken at least [illegible] hour before the resins

Dose and costs Begin with one 4 gm. s[illegible] *before* each meal (three times daily) and this [illegible] may be doubled or even tripled in adults [illegible] January 1980 the cost *to our pharmac*[illegible] $48 18 per 100 sachets

Nicotinic acid This is a vitamin of the B [illegible] (niacin) which prevents pellagra given in [illegible] larger doses to reduce plasma lipids.

Indications Nicotinic acid is the only [illegible] lowering drug which is highly effective in re[illegible] both plasma cholesterol and triglyceride leve[illegible] is indicated in hypercholesterolemia hyper[illegible] glyceridemia and combined hyperlipidemia, p[illegible] sibly in combination with other drugs (see Ta[illegible] III)

Effect Nicotinic acid lowers plasma choles[illegible]

Table II Effect of clofibrate neomycin and colestipol therapy on body masses of cholesterol

Study	n	Ma (gm)	M (gm)	M Ma† (gm)
Control		38	109	71
Clofibrate	5	28	77	49
Difference (%) (Ref 5)		10 (26)	32 (?9)	22 (31)
Control		36	103	67
Neomycin	4	22	0	48
Difference (%) (Ref 16)		14 (39)	33 (3?)	19 (28)
Control		24	5?	31
Colestipol	7	23	55	32
Difference (%) (Ref 17)		—	—	—

Ma = Rapidly exchangeable pool of cholesterol (Plasma + RBC + liver + gut)
M = Minimum estimate of total body mass of cholesterol (except CNS).
† M = Slowly turning over masses or tissue cholesterol.

vels by about 8% to 16% and triglycerides by ?% to 30% It lowers plasma free fatty acids VLDL and LDL and it increases HDL levels[8]

Mechanism of action It is frequently stated to be unknown Nicotinic acid was shown to decrease lipolysis decrease the hepatic production of triglycerides and increase fecal excretion of cholesterol end products (neutral sterols)

Side effects are unfortunately numerous and patient acceptance is poor It seems to me that for this reason the drug is only a second line compound The main problem is intense cutaneous flushing and pruritus Starting with small doses (100 mg in the middle of meals) and increasing the dose gradually may somewhat alleviate this symptom Anorexia nausea vomiting diarrhea and activation of peptic ulcer have been reported Glucose intolerance impaired liver function tests and hyperuricemia may also occur

Drug interactions May potentiate the effect of vasodilator drugs or hyperuricemic diuretics

Dose and costs Begin with 100 mg tablets three times daily and increase gradually to one gram (two 500 mg tablets) in the middle of three meals (3 gm per day) In January 1980 the cost to our pharmacy was $1 50 per 100 (500 mg) tablets

Neomycin Neomycin is a broad spectrum aminoglycoside antibiotic poorly absorbed from the gastrointestinal tract (< 3%) It lowers plasma cholesterol levels at very low doses of administration (0.5 to 2 gm daily)

Indications Hypercholesterolemia

Effect The drug reduces plasma cholesterol levels by 20% to 30% sometimes even in patients with resistent familial hypercholesterolemia[6]

Mechanism of action Neomycin decreases cholesterol absorption and increases fecal cholesterol end product (neutral sterol) excretion leading to a negative sterol balance[1] Its effect may be mediated through its action on the intestinal bacterial flora (markedly decreased 7α-dehydroxylase activity of intestinal bacteria) or by interfering with micelle formation in the lumen of the gastrointestinal tract

Side effects One third to half of patients on neomycin have transitory diarrhea or abdominal cramps that usually subside after 1 or 2 weeks Lomotil is helpful for this symptom The small amounts of neomycin absorbed from the gut are excreted by the kidney thus normal renal function is an absolute prerequisite for using the drug Ototoxicity has been reported in very rare cases we perform periodic hearing tests in patients treated with neomycin At higher dose levels (12 gm daily) steatorrhea renal damage staphylococcus enterocolitis moniliasis and multiresistant coliform overgrowth have been reported however we have not observed these complications with the small doses used for cholesterol reducing purposes[12]

Drug interactions Digoxin should be administered one hour before neomycin is given inasmuch as there may be interference with its absorption The possibility exists that coumarin anticoagulants may be potentiated by the drug

Dose and costs Tablets of 0.5 gm of neomycin sulfate three or four times daily after meals (two

Annotations

Coxsackieviruses and chronic valvular heart disease

Acute rheumatic carditis of streptococcal etiology is considered to be the predominant cause of chronic valvular heart disease (CVHD). Hence there is a tendency to assume that all or most cases of CVHD are of rheumatic origin. This has resulted in an inadequate search for other possible etiological factors in CVHD.

It is now clear that several infectious agents can cause endocarditis and valvulitis in man and animals. These agents are group B coxsackieviruses (CBV), adenovirus, encephalomyocarditis virus, virus III, inflammatory fibroma virus, vaccinia virus, pseudorabies virus, varicella virus, *Chlamydia psittaci*, *Coxiella burnetii*, and *Mycoplasma gallisepticum*. Among these CBV form an important group.

The relationship between viruses and CVHD may be investigated (1) in experimental animal models, (2) by following up the clinical course of individuals with viral myocarditis, and (3) by investigating patients with CVHD.

Endocarditis and valvulitis are caused by CBV infection in mice and in cynomolgus monkeys. They also cause CVHD in cynomolgus monkeys with pathological changes similar to those of human rheumatic heart disease.

In human viral myocarditis the cardiac valves may be affected either directly as a result of valvulitis or indirectly by the involvement of the valve ring and the valve apparatus due to cardiac dilatation. It would be reasonable to assume that the more severe the myocarditis, the greater the likelihood of valvulitis and consequent CVHD. However, an evaluation of the published reports of the follow up of patients with viral myocarditis has been difficult because the data available are incomplete. Babb and colleagues reported on four patients ranging in age from 4 to 19 months with CBV myocarditis. A 1? month old child had no murmur on the phonocardiogram and only a slight cardiac enlargement seen on the chest x ray at the time of his acute illness. However, this child had an apical systolic murmur without cardiac failure 4 months later. The second patient, a 9 month old infant, had a normal chest x ray and ECG, but the phonocardiogram showed a mid dia[illegible] murmur of the ejection type [illegible] the acute illness. Five months later there was still a slight [illegible] murmur. The third patient was a 4 month old infant wh[illegible] chest x ray and ECG but wa[illegible] had a blowing systolic murmur. Th[illegible] the twelfth day and the child wa[illegible] well [illegible] evidence of [illegible] [illegible]rth patient had no [illegible]

Smith report[illegible] [illegible]BV myocarditis four of whom had [illegible] these patients had enlarged hearts an[illegible] third had only an abnormal ECG [illegible] had a pansystolic murmur followed [illegible] short mid-diastolic murmur presumed [illegible] viral infection. This patient was later admitted for a proved viral myocar[illegible] to CBV type 4. There is no mention of perm[illegible] damage during follow up. In a later repor[illegible] there were ?3 with myocarditis and residual card[illegible] with or without mitral incompetence.[illegible] Clinical deta[illegible] ing admission were incomplete.

Sainani and co workers[illegible] have reported on [illegible] proved CBV myocarditis of whom eight had [illegible] murmurs including one with an apical mid-dia[illegible]. There was diffuse cardiac enlargement in 1? cases [illegible] clinico radiological correlations were given. Of the [illegible] followed up, one had a systolic murmur f[illegible] another for 19 months and a third had a [illegible] mid-diastolic murmur for 6 months. In a later [illegible] India there were 19 patients with CBV myocard[illegible] whom 13 had Grade 2/6 apical systolic murmurs [illegible] acute stage. None of them had murmurs during [illegible] up.

Bengtsson studied 90 patients with cardiac [illegible] following infectious diseases, of whom ?4 had a variety of infections. A systolic murmur was present in [illegible] patient had diastolic murmurs. The persistence of [illegible] involvement is not mentioned in their report.

Gerzen et al.[illegible] reported on the follow up of [illegible] acute myocarditis, ? of whom had a viral etiolog[illegible] them had evidence of valvular involvement.

Thus the reports on patients with CBV myocard[illegible] that valvular involvement in the acute phase [illegible] quent. However, the follow up reports do not give [illegible] picture of the frequency of CVHD. Myocarditis d[illegible] viruses seems to be less often associated with val[illegible] ment.

Burch and colleagues,[illegible] using immunofluorescent [illegible] nique studied 5? routinely autopsied hearts. CBV [illegible] were found in the myocardium in 30.9% and in the [illegible] dium and valve in 5.45%. The prevalence was [illegible] children than in adults. Later Burch and Colcolough [illegible] onstrated CBV type 4 antigen in the areas of [illegible] damage including the aortic valve in a pa[illegible] regurgitation, myocarditis and nephritis.

Ward and Ward examined left atrial and [illegible] specimens from patients with CVHD by [illegible] flourescence for the presence of antigens of a variety of [illegible] (polio types 1 3, influenza A, echo type 16, CBV [illegible] *Chlamydia psittaci* and *Mycoplasma pne[illegible]* [illegible] antigen was found in one or more cases. [illegible] positive for two or three unrelated antigens. There [illegible] difference in the frequency of detection of a[illegible] with and without a history of rheumatic fever.

Thus the investigations on patients with CVHD g[illegible] support to a possible virus etiology in val[illegible] Further evidence for CBV involvement in the [illegible]

Cardiopulmonary resuscitation—an element of sophistication in the 18th century

Drowning or near drowning accidents appear to have been as prevalent in the 1700s as they are today Interest in the aggressive treatment of drowning or near-drowning victims has always been great for these individuals were usually in good health and because it has become apparent that survival is possible even after as long as 40 minutes below the surface Eighteenth century reports of survivals after hours under water have been noted but of course would be difficult or impossible to confirm During the latter half of the 18th century however elements of the pathophysiology of drowning were recognized Hosack discusses popular opinions by "distinguished writers" on the subject that in essence point to the primacy of hypoxemia— it is probable that the death which ensues or seems to ensue in drowned persons is entirely owing to the stopping of respiration and to the ceasing in consequence of the circulation of the blood Laryngospasm was also recognized— a contraction of parts about the larynx preventing the air from passing into or out of the lungs The lack of significant amounts of water in the lungs of some individuals ... was also known

The interest ... for providing assistance to the drowning ... the establishment of societies in the ... (Humane Societies) first in Amsterdam then in ... European capitals and finally in the United ... societies which were also concerned with ... death procured books and manuscripts ... resuscitation procured and kept in good ord... published medical advice on related ... all successful and unsuccessfully tr... in essence stimulated research and new appr... treatment ... prizes and monetary grants to th... contributions to the already existing knowledge ... It was claimed by Hosack that nearly one thousand persons were ... from death in a 20 year period by the societies in ... and London

ble I Geometric mean titers of antibody to
up B coxsackieviruses

	Type					
	B1	B2	B3	B4	B5	B6
-matched control (n = 58)	13	16	11	18	10	8
HD with h/o R F (n = 12)	14	26	33	49	10	14
HD without h/o R F (n = 16)	8	26	44	74	8	12

o R.F = history of rheum tic fe er CVHD = chronic valvular
rt disease

HD was the subject of a recent preliminary report by us a from 29 patients with mitral stenosis and from 58 matched controls were examined for the prevalence and rs of neutralizing antibodies to CBV types 1 6 There e statistically highly significant differences between ients and controls in the titers of antibody to CBV type 3 l 4 and in the prevalence of antibody to type 3 Among the ients 12 had a previous history of rheumatic fever and 16 not In one patient the history was equivocal The metric mean titers of antibodies in these patients are wn in Table I Clearly the mean titers of antibody to CBV es 3 and 4 were considerably higher in patients without a tory of rheumatic fever than in those with such history

some patients with CVHD do not have a history of eumatic fever While there has been a reported decline in prevalence of acute rheumatism and consequent CVHD decline in the prevalence of CVHD without preceding umatic fever has been observed This further supports the ncept of nonrheumatic CVHD which is embodied in newer rms such as "rheumatic type" valvular deformity and rus valvular heart disease

It is also possible that in some cases of CVHD the valve formity may be the result of damage produced by sequential t subclinical attacks of rheumatic and/or virus valvulitis rhaps such valvular deformity is more commonly stenotic her than regurgitant for the following reasons It is the tient with mild rheumatic carditis who is more likely to velop a stenotic valvular lesion On the contrary those with rurgitant valvular deformities more often give a history of eceding severe rheumatic carditis It is also known that tients with stenotic valvular lesions give a history of acute eumatism less often than those with regurgitant valvular sease

More intensive studies on a large number of patients with notic and regurgitant valve deformities and a follow up of ose with proved viral myocarditis for evidence of presistent lvular disease may result in a change of our present owledge on the etiological factors responsible for chronic lvular heart disease

sorders associated with that state The concept of closed iest cardiac massage was not recognized in the 18th century it a need to do something for the cardiac situation no doubt d to the recommendation for the use of electricity Hosack fers that the rationale for the use of electricity was its then ll established and well recognized action on the muscle er It was in the 1780s that Galvani observed that by uching the nerves or the muscles with a piece of metal onnected to an electrostatic machine the muscles could be ade to contract The Humane Society of New York believed ectricity to be a most powerful agent a very proper medy" The society warns however that in all ca es the achine should be made to excite powerfully otherwise the tempt to use it will be a loss of time and so the precious oments of recovery may be lost forever A procedure was itlined by which the patient was "electrified for four or five inutes the hand of one of the attendants being applied close the body so as to take strong sparks which should be awn from the left side over the heart If that procedure did ot produce the appearance of life or motion they recom ended that light shocks (which should be increased each eration) should be sent from the breast bone through to the ick or from side to side so as to excite the heart to action if ssible This latter effort would certainly appear to be in ie with our present day concepts of closed chest cardiac imulation as demonstrated by Zoll. These early investiga ors did warn of the need for this procedure to be performed ily by experienced operators Hosack also warns that to get i electrical apparatus in readiness requires a considerable ngth of time especially on a damp day in which time the tent spark of life may be entirely destroyed On reading the ove one cannot help but wonder whether these patients on casion and quite fortuitously might have been helped by fibrillation (we are all aware of how small a shock is casionally effective in cardioversion of various arrhythmias) or periods of cardiac pacing (the repeated light shocks applied to the chest) Could the latter have been the forerunner of the external pacemaker a concept which did not become a reality for another 150 years?

How many lives were actually saved by these methods would be impossible to estimate One cannot help but be impressed by the degree of sophistication suggested by the practitioners of that period Principles and therapeutic inter ventions common to the practice of cardiopulmonary resusci tation that most would have associated with modern medical practices, were actually in vogue almost 200 years ago

rrors in predicting functional capacity from treadmill exercise stress test

xercise stress testing as a diagnostic procedure for ischemic eart disease has been used by qualified physicians for many ars Since physical activity has been shown to be a useful odality for improving functional capacity in cardiac itients, knowledge of the individual s aerobic level and heart ite response is essential if such prescribed activity is to be lministered safely and effectively Though direct oxygen onsumption measurements are more accurate than predicted alues, especially with cardiac patients the additional equip ent and procedural requirements make such an evaluation either practical nor economical in many clinical situations s a result nomograms, tables and formulae have been eveloped for estimation of the patient s ability to use oxygen uch estimates have been derived from exercise of a highly andardized nature It has been suggested that wide varia tions about estimated values can be expected especially if protocols used for particular nomograms or tables are not strictly followed Thorough documentation of these varia tions have not been reported The purpose of this investigation was to compare oxygen consumption values during a progres sive treadmill exercise stress test while either allowing sub jects to use handrails for enhanced stability or not allowing such assistance

Six healthy male volunteers who were classified as follow ing an active lifestyle but who were not considered to be in a trained state were used as subjects Their characteristics expressed as mean values were age = 26 6 (± 2 1) years weight = 71 5 (± 3 3) kilograms percent body fat = 12 (± 2.3) and maximum oxygen consumption = 48 1 (± 5 9) ml /kg minute In each case the subject worked to maximal

Alcohol and coronary heart disease

Several epidemiologic studies have suggested that men who consume small to moderate amounts of alcohol daily have a decreased risk of coronary heart disease (CHD) This relationship deserves careful assessment both because of the high frequency of CHD and the documented health hazards of excessive alcohol consumption

Our recent study of 568 married white men who died from CHD and an equal number of matched controls found that those drinkers who consumed two ounces or less of alcohol per day had a significantly lower risk of CHD as compared to non drinkers This finding was similar for beer wine and liquor As compared to non-drinkers, the relative risk of death from CHD for light to moderate beer drinkers was 0 3 for wine drinkers 0 3 and for liquor drinkers it was 0.2 In contrast consumption of more than two ounces of alcohol per day in the form of any of these three types of beverages was clearly not associated with any reduction in coronary deaths and may have been compatible with an increase in risk.

These results are consistent with those of three prospective cohort studies the Framingham Heart Study the Kaiser Permanente Study and the Honolulu Heart Study In the Framingham data the relative risk of myocardial infarction (MI) for consumers of more than 30 ounces of alcohol per month was 0 The data from Japanese men in Hawaii showed a linear protective effect of alcohol with a relative risk of 0 46 in those consuming more than 40 ml per day This effect was limited to current drinkers the relative risk in past drinkers was 1 3 The association in the Kaiser data was statistically significant but as presented it did not permit calculation of a relative risk estimate

On the other hand the Western Electric Study[4] did not show any relation of CHD to alcohol consumption but the amount of alcohol [illegible] specified and it is not clear that the analysis was [illegible] A positive relation of alcohol consumption to MI was noted in a small Swedish cohort study [illegible] was defined by registration with a [illegible] however the subjects denoted as con[illegible] have been heavy drinkers A recent case-control study of 4[illegible] hosp[illegible] of non fatal MI and 2 5[illegible] controls concluded [illegible] any major over all association but tended to [illegible] inverse relation with moderate alcohol consumption [illegible] protective effect was primarily noted in smokers [illegible] relative risk was 0 [illegible] as compared to non-drinkers [illegible]

The biologic basis for the effect of alcohol on CHD [illegible] uncertain but one possible mechanism may be [illegible] lipids caused by alcohol In one experimental [illegible] Swedish medical students consumed 6 g of alcohol [illegible] five week period During this time the alpha [illegible] level itself a preventive factor for MI increased [illegible] imately 30% above baseline The Cooperative Lipoprotein Phenotyping Study has found a consistent positive [illegible] between alcohol consumption and high density lipoprotein levels in various parts of the United States, with [illegible] coefficients ranging from 0 19 to 0 [illegible] This [illegible] found an inverse association between alcohol [illegible] and low density lipoprotein levels, although the [illegible] was not as strong Henze and associates have [illegible] association between the amount of wine consumed [illegible] alpha lipoprotein level in a cross-sectional study [illegible] Roman males Using a five-level categorization of [illegible] sumption the correlation with alpha lipoprotein [illegible] 0 13 Our most recent data for a group of [illegible] shows both elevated HDL levels as well as [illegible] alcohol consumption. In addition large doses of [illegible] cause alterations in platelet aggregation [illegible] platelets or regular consumption of small [illegible] amounts of alcohol are unknown but platelets [illegible] a role in the pathogenesis of MI and platelet [illegible] decrease risk of MI [illegible]

The effects of alcohol on CHD may not be [illegible] direct mechanisms, however Of special interest [illegible] tionships of alcohol and CHD to personal [illegible] and diet Much of the apparent effect of alcohol on CHD [illegible] be explained by its association with other variables [illegible]

Several studies have suggested an [illegible]

0002-8703 80 100 [illegible] 0[illegible] The C V Mosby

otocols were 15 ± 2 76 minutes and ?5 2 ± 7 16 minutes spectively

Allowing patients to grasp handrails for support during a eadmill stress test is often necessary In this study subjects ere discouraged from applying tension to their grip during ie handrail assisted condition though this factor was not iantitated

With the substantial reduction in oxygen cost and heart te at any given submaximal load when using the handrail r support one would expect to see an increase in exercise iration When one considers the importance of duration in timating oxygen cost from published tables close tention should be paid to factors altering this parameter ermitting handrail support also conflicts with the assumpons of Balke and Ware in calculating oxygen cost from eadmill speed and grade The use of heart rate as an *dicator of symptom onset and intensity when writing an* tercise prescription is also adversely affected by such a ipport type protocol

As a result of the data presented it is apparent that curate determination of those values necessary for safe and fective prescription writing is not possible unless direct ieasurement is made or unless strict adherence to specified rotocols is maintained This appears to be of major impor ince when dealing with cardiac patients In this study using oung healthy subjects the average error in prediction of V O hen duration was used as the index was 17.5% A erage eart rate values showed a 9 5% deviation Considering that iese values were in the direction of indicating a greater apacity than really existed serious attention should be paid o treadmill test protocol administration

f the mitral valve and arrhythmias

: recently exaggerated and often unfounded diagnosis of lapsed mitral valve with associated arrhythmias especially tricular premature contractions stimulates thought as to iossible mechanism for the arrhythmias claimed to be ited to prolapsed mitral valve leaflets It is unlikely that tension alone which is associated with the time course of rease in intraventricular pressure during systole is respon e for even occasional premature contractions The tension :he annulus cannot be any greater than ordinary If there eally a cause and-effect relationship there must be another tor involved Any explanation at this time can only be ijectural To conjecture is permissible if the conjecture is at st thought provoking

:t is known that independent electric activity does exist in muscle fibers of the mitral valve Muscle fibers in the tricuspid valve leaflets have been shown to develop spontaneous action potentials in response to stretch and catecholamines This same type of spontaneous action potential activity has been detected in the cardiac muscle fibers of the simian mitral valve In both reports sustained rhythmic activity has also been described Wit and Cranefield have found the electric activity of the cardiac muscle fibers in the pigtail monkey to be triggerable even with the development of sustained rhythmic activity Verapamil will abolish this activity induced by catecholamines Cranefield has described characteristics of the action potential trace

Thus, it is possible that more arrhythmias may develop with disease *and/or structural changes and hydraulic* dysfunction

Antithrombotic therapy for saphenous vein bypass grafts?

Closure of saphenous vein aortocoronary bypass grafts has been shown to occur in 19% of transplanted vessels within six months although current occlusion rates are lower Improved graft patency should increase the clinical benefits of this surgical procedure It is possible that the isolation preservation and subsequent transplantation of an autologous segment of vein into the arterial circulation leads to endothelial damage which then sets the stage for thrombotic graft occlusion due to platelet accretion and/or fibrin deposition Consequently we recently completed a randomized and controlled trial to determine whether anticoagulant or antiplatelet therapy would significantly reduce the incidence of vein graft thrombosis within six months of surgery

In this study patients undergoing bypass grafting for coronary heart disease were randomly given oral anticoagulants (warfarin sodium) antiplatelet drugs (aspirin 300 mg and dipyridamole 75 mg three times daily) or no therapy and were evaluated for graft patency by coronary angiography six months later An analysis after 50 patients were entered indicated no clinical benefit from these interventions and further that there was a greater than 90% certainty that continuing the trial would fail to improve graft patency rates in the treated groups

Why did the antithrombotic therapy fail to improve graft patency? Perhaps the selected drugs were ineffective Currently available antiplatelet agents seem to vary markedly in their pharmacology and spectrum of clinical utility For example sulfinpyrazone showed a distinct benefit in the Anturane Reinfarction Trial but had no effect in reducing mortality in Canadian patients with transient ischemic attacks Secondly starting treatment three days after surgery may have been too late if thrombosis occurred just after graft implantation Other investigators gave antiplatelet drugs prior to operation but were disheartened by excessive blood loss at surgery Third the dose of aspirin used in our trial may have been either too high or too frequent in light of the differential effects of aspirin on prostaglandin synthesis in endothelial cells and platelets Fourth technical or mechanical factors surrounding the implantation of the vein and poor blood flow in the graft due to distal coronary artery disease may be so thrombogenic that none of the currently available antithrombotic drug regimes will be effective However a recent abstract which outlined a study in whi h ulfinpyrazone was given to patients undergoing vein grafting provides a less pessimistic view Finally vein graft patency rates may have improved due to better surgical techniques so that an additional benefit of pharmacologic therapy is difficult to show For ex... patency of vein grafts to the left anterior descending coron... artery in our study was 9?%

Even though our clinical trial showed no benefit from ... antithrombotic therapy the results were still rewarding ... other information is available patients should be spared unnecessary expense and risks of bleeding from anticoagulant or antiplatelet drugs given to improve graft patency

Future studies could profitably be directed toward ... tive protocols using antiplatelet agents in clinical tr... Particularly welcome would be the development and ... tion of noninvasive techniques to assess platelet reactio... graft patency thereby sparing subjects the risks and ef... forts of repeated coronary angiography

.,_ A behavior pattern in men and the risk of MI One might ›eculate that some feature of this pattern makes these men ss likely to be light to moderate consumers of alcohol or lternatively that alcohol consumption may modify behavior atterns The relation of Type A behavior pattern to alcohol itake is not clear and studies of behavior patterns and CHD ave not included quantitative data on alcohol consumption ome investi ations have suggested that coronary e ent iay be preceded by an increase in the number and severity of fe changes although this association ha not been found in ll studies[20] Again it is possible that such life changes may lter alcohol consumption or themselves may be affected by ise of alcohol It is also necessary to consider alcohol as a ietary component and weigh the effects of alcohol consump-ion on the intake of other nutrients. This task is complicated oth by continuing uncertainty over the role of diet in CHD nd by the problems of measuring dietary intake in epidemio-ogic studies

Understanding of the relationship of alcohol to CHD would e substantially advanced by studies considering the variables ioted above. It would also be advantageou to have more data n the association in women In addition the possibility of nteractions between alcohol consumption and known risk actors for CHD such as cigarette smoking deserves investiga ion The benefits and disadvantages of an agent are often best letermined by a well-designed randomized treatment trial ind after careful consideration of the ethical and practical ssues, such an evaluation of alcohol consumption might well e informative

Currently when advising patients concerning alcohol the mphasis should remain on the many documented adverse ffects of excessive use of alcohol, including the risk of nyocardial disease[21] We do not think that there is evidence it this time to claim preventive or therapeutic benefit for light o moderate use of alcohol for coronary disease Caution is varranted both because our understanding of the relation of ilcohol to CHD is insufficient for the reasons noted above ind because the general problem of translatin epidemiologic bservations to therapeutic intervention applies especially to ilcohol with its complex metabolic physiologic and psycho ogic effects Even if one believes that the statistical associa ion is causal, the words of Ca telli seem well chosen with ' million alcoholics in this country we perhaps have a ssa e for which the country is not yet ready

nificantly less than the control value In spite of this the arterial blood pressure did not fall It should be noted that the left ventricular stroke work index at exercise was significantly improved compared to the control value Unlike the results following isoproterenol and hydralazine administration the patient did not demonstrate a resting tachycardia on either the initial catheterization or on follow up

Diazoxide is a direct vasodilator that produces a secondary increase in cardiac output due to a decrease in the afterload in the pulmonary circulation The increase in the cardiac output with diazoxide appears to be better than that seen with other vasodilators and may represent a direct inotropic action of the drug

In summary the value of isoproterenol and oxygen therapy is limited while phentolamine hydralazine and diazoxide show promise Diazoxide would appear to have some advantages since it is the only drug out of the three that causes a significant decrease in the resting pulmonary artery pressures in addition to the decrease in pulmonary arteriolar resistance and increase in the cardiac output Also since sudden death is an important feature of the syndrome the arrhythmogenic potential of resting tachycardia as seen with hydralazine must be considered

The initiating cause for primary pulmonary hypertension may vary in each patient and therefore the response to these various medications may differ Accordingly acute drug testing with these medications with later follow up may allow selection of the most appropriate drug in the individual patient Certainly the results in our study and those of Wang and colleagues indicate that further evaluation of diazoxide in primary pulmonary hypertension is warranted

Of walking and dyspnea of congestive heart failure

The role of the veins in regulating the two cardiac pumps (right and left ventricles) and the flow of blood is frequently ignored The veins are the great reservoirs of the body s blood Much of the blood is stored in the legs When people walk the venous pumps in the legs readily force blood toward the heart and into the lungs since there are no valves in the heart to prevent the gushing blood from entering the lungs This shifted volume of blood is returned to the systemic venous circulation and [illegible] there when the function of the two pumps is well b[illegible] and synchronized But when there is left ventricular congestive heart failure this synchronization and balance of the two pumps (right and left ventricles) is lacking and the blood shifted to the lungs tends to accumulate in the lungs and cannot be shifted back into the tight systemic veins present in CHF The blood is not "stored in the systemic veins as is true normally Thus the pulmonary circulation remains over-engorged and the patient with left ventricular CHF becomes quite dyspneic not only because of failure of the left ventricular pump but also because of the pumping of blood or shifting of blood into the lungs by the venous pump in the legs upon walking or skeletal muscle contraction The blood returning from the arterial system cannot accumulate sufficiently in the tight systemic veins so characteristic of CHF

Physicians usually attribute the increase in dyspnea and development of dyspnea with walking (leg exercise) to the precipitation or worsening of left ventricular congestive heart failure as a result of the added work imposed on the heart

atment for primary pulmonary hypertension

tact mechanism for primary pulmonary hypertension is wn. It is felt to be due to an inappropriate vasoconstric the pulmonary circulatory system Postulated mecha of the increase in the pulmonary artery pressure and nce characterizing this disorder include locally pro vasoconstricting substances as well as the possibility he disease may be of autoimmune origin The end result tter what the initiating cause is a progressive increase in nary vascular resistance with a concomitant and signif lecrease in cardiac output resulting in symptoms of poor ion and eventual right ventricular failure and sudden . Most of the patients studied have been young females nbing to the disease in an average of seven years

h this in mind various vasodilators have been tried include tolazoline acetylcholine oxygen and isopro ol[1-] However attempts to halt progress of the disease hese drugs have been unsuccessful.

asaka and colleagues reported a patient treated with n and phentolamine The use of oxygen alone did not cantly lower the pulmonary artery pressure while he awake With the addition of phenoxybenzamine the nary artery pressure did decrease while the patient was but not while he was awake However the pulmonary lar resistance decreased to one half the resting value At ly one month and eight months later the pulmonary pressure had returned to control values in spite of a nued decrease in the pulmonary vascular resi tance is no mention of any change in the cardiac output In a involving six patients with primary pulmonary hyper n Daoud and associates found that there was no icant and predictable response to oxygen therapy Therehe value of O therapy by itself is doubtful.

ravenous isoproterenol has been advocated by a number ithors.[1-] The response to acute treatment with this ration is variable with only two out of six patients ed by Daoud and co-workers[3] respondin, and with only atient with a response to sublingual isoproterenol In this nt the symptoms continued to progress and required five hospitalizations for acute intravenous therapy A nt studied by Shettigar and colleagues showed the same l favorable response but then a later progression despite nued therapy In both these studies significant resting cardia was observed Thus the variable response tachy a tachyphylaxis, and repeated use of intravenou admin tion was seen to limit the usefulness of isoproterenol.

cently there have been reports of the effectiveness of tolamine hydralazine and diazoxide[4-] in primary pulmonary hypertension Phentolamine both intravenously and orally has been used by Ruskin and Hutter[4] to treat a patient with typical primary pulmonary hypertension. In their patient intravenous and oral phentolamine both acute ly and chronically failed to significantly reduce the resting pulmonary artery pressure and only moderately decreased the pulmonary vascular resistance However their patient dem onstrated a significant and pronounced decrease in these indices with exercise and this effect was well preserved when the patient was restudied six months later In addition there was a significant increase in the cardiac output at both rest and exercise. A recent report by Rubin and Peter[4] outlined their use with hydralazine in four patients. The pulmonary vascular resistance decreased both at rest and exercise with a concomitant increase in cardiac output. However there was no significant decrease in pulmonary artery pressure at early and late follow up All patients had a significant increase in the resting heart rate at rest Thus, although hydralazine and phentolamine can decrease the pulmonary arteriolar resistance both acutely and chronically the continued high pulmonary artery pressure may result in continued strain on the right ventricle and further progression of right ventricular failure The patients in both studies improved symptomatical ly throughout the period of follow up Whether this will continue without further increase in the dosage of the medi cation remains to be seen

Diazoxide has been used by both Wang and colleagues and by us with similar results. In our study we administered intrapulmonary artery diazoxide to a young female who had both the clinical and objective findings of significant primary pulmonary hypertension. The pulmonary artery pressure fell from 63/30 (39) to 42/22 (28) with a concomitant decrease in the pulmonary arteriolar resistance from 430 dynes/sec./cm to 115 dynes/sec /cm In association with this, there was a marked increase in the resting cardiac output from 4 8 L/ minute to 10 4 L/minute There was no significant tachycardia at rest. The patient was then placed on oral diazoxide 300 mg. a day and was restudied six months later During this period and since the follow up catheterization, the patient has remained asymptomatic At restudy the pulmonary artery pressure was 41/19 (27) and increased to 55/29 (38) with exercise The pulmonary arteriolar resistance increased from 18_ dynes/sec./cm to 195 dynes/sec /cm with exercise Of significance was the fact that the cardiac output at rest remained high at 8 3 L/minute and increased significantly to 13.1 L/minute with exercise Throughout the study the systemic vascular resistance remained normal, although sig

Correlation between exercise hemodynamics and increased magnitude of P terminal force

To the Editor

We have reviewed with interest the paper by Di Bianco and associates "Left atrial overload A hemodynamic echocardiographic electrocardiographic and vectorcardiographic study" (AM HEART J 98 478 1979)

Their results are similar to those of a study we have previously published but that was apparently overlooked by them. Our results were in general agreement with theirs except that we found a significant correlation between the PTF V and the *exercise* PA wedge pressure and not the *resting* PA wedge pressure. None of our patients had acute myocardial infarction and all had chronic stable angina. If patients with acute infarction are excluded it is likely that the resting PA wedge pressure may not correlate with the PTF V

Reply

To the Editor

We would like to thank Drs Shettigar and Hultgren for bringing to our attention their published work. In patients with stable angina pectoris these authors demonstrated a correlation between the PTF V and the pulmonary artery wedge pressure during exercise but not at rest. Other findings in their study of patients with stable angina pectoris are supported by our evaluation of a broader patient group which included patients with acute myocardial infarction, primary myocardial disease and other disease entities. Both studies reveal the lack of correlation between hemodynamic measurements and echocardiographically determined left atrial size or P wave duration. However 11 of the 61 patients in our study had acute myocardial infarction and the question has been raised whether exclusion of this patient group might alter the significance of the correlation between the pulmonary capillary wedge pressure at rest and the PTF V. Review of our data reveals that 42 of 50 patients without acute myocardial infarction had ... of the pulmonary capillary wedge pressure and the PTF V as opposed to 9 of the 11 patients with acute myocardial infarction (p = NS). Pulmonary capillary wedge pressure and PTF V in patients without acute myocardial infarction (n = 50) were significantly related (r = 0.69 ± 0.035 SEM); this correlation did not differ from the over all group

The hypothesis that chronic intermittent increases in left atrial pressure result in the increased magnitude of the P terminal force in Lead V in patients with ischemic heart disease is tenable. It seems clear that the surface electrocardiogram for whatever reason reflects alterations of interatrial conduction time as was pointed out by Josephson and associates

Function testing soon after acute myocardial infarction

To the Editor

Recently Theroux and colleagues showed function testing (low level exercise stress testing) performed before hospital discharge after acute myocardial infarction (A M I) is safe and can predict mortality in the subsequent year. These workers showed that the one year mortality rates were [illegible] in patients without changes in the ST segments and 2[illegible] in patients with depression of the ST segment (p < [illegible]). Because of the prognostic value of this test we were interested to learn how often a function test resulted in a change of management in patients recovering from an acute ischemic event

We examined 82 sequential function tests performed on male and 16 female patients of mean age 59 7 years (range [illegible] to 88 years) who achieved a mean M E T level of 3 [illegible] (range 1 7 to 11) on testing. Seventy three patients ([illegible]) were post-coronary recovering from an A M I, six (7.3%) were post-coronary artery bypass graft surgery (C A B G) and the remaining three patients (3 7%) had suffered an acute ischemic episode. The mean days of study was hospital day 13.3 (9 to 34 days), for the A M I patients hospital day 18.8 (10 to 34 days) C A B G patients and hospital day 11 0 (6 to 14 days) ischemic episode patients. No morbidity or mortality was seen

art by the exercise Both the cardiac pump and the venous mp are mutually contributing factors, but the role of the nous pumps in the legs and other systemic veins must not ignored in CHF The role of the venous pumps must be nsidered when explaining the dyspnea and other clinical anifestations of CHF associated with walking

heart block Unfortunately the skin overlying the box became necrotic and the pacemaker box had to be exchanged but the electrode could not be removed and was left in situ

Nine months later the patient presented with pleuritic chest pain and screening showed that the abandoned electrode had migrated into the right ventricle and that the cut end of electrode had penetrated the free wall of the heart He developed signs of pericardial tamponade and required an emergency thoracotomy at which time free blood was found in the pericardial sac The redundant wire was removed and the patient made an excellent recovery

This case re-emphasizes the need for secure fixation of the cut end of retained electrodes

To the Editor

We appreciate the interesting comments of Drs Perel[illegible] and Shiu whose case report on cardiac tamponade due [illegible] catheter perforation of the right ventricular free wall confi[illegible] the conclusions drawn in our recently published manus[illegible] from similar experiences (AM HEART J 98 58 1979).

However we should like to point out that in our report[illegible] case on catheter embolization into the pulmonary artery the electrode wire was not retrieved via thoracotomy as erro[illegible]ously quoted by Drs Perelman and Shiu but in fact had to b[illegible] left in situ since thoracotomy was refused by the patient; h[illegible] died suddenly several days later

Table I

	No. of patients
New arrhythmia resulted in medication or change in medication	5
Chest pain resulted in change of medication	4
ST segment depression resulted in coronary angiogram	4
No new arrhythmia while on medication and therefore continued same	3
Chest pain resulted in a coronary angiogram	2
Blood pressure drop resulted in angiogram	2
Diminished exercise tolerance resulting in ordering a cardiac rehabilitation program not previously planned	2
Dizziness resulted in delay of discharge	1
Total	23/82 (28%)

The reasons for stopping the test were that the target heart rate was achieved in 41 patients (50%), symptoms of dyspnea, fatigue, and leg weakness were seen in 21 patients (26%), chest pain was found in eight patients (9.8%), ST drop greater than 1½ mm appeared in seven patients (8.5%), arrhythmia was found in three patients (3.7%), and a significant blood pressure drop was seen in two patients (2.4%).

We found that in 23 of the 82 patients (28%) the performing of a function test resulted in a change in the management of the patient by the attending physician. The reasons for a change in management by the attending physicians are shown in Table I.

Thus in addition to predicting prognosis, function testing before hospital discharge resulted in a change in patient management in 28% of our patients. Function testing also allows an objective evaluation of a patient's response to low level exercise that he will experience in his home environment and allows the physician to more accurately determine the type of activities permissible for the patient at home. It also seems possible that in the future function testing may play an important role in determining which patients should have coronary angiography prior to discharge.

Of bibliographies and medical librarians

To The Editor:

This letter is written in response to the Annotation entitled "Of bibliographies" (AM HEART J 99:401, 1980). The point made by Dr. George F. Burch that authors do not always research their topic adequately is well taken. As the editor of AMERICAN HEART JOURNAL, Dr. Burch is obviously in a position to observe the quality of literature research done by his colleagues. It is also true that a "careful review of the medical literature on any subject is an ordeal which is difficult and time-consuming." Our role as medical librarians is to aid those authors who do not have the time to do extensive research. If a physician feels that the Medline search is not adequate or preferred, most librarians will be happy to do a manual search and/or provide instruction so that the experience can be "informative, educational, and proper," as Dr. Burch suggests. Medical schools which include a segment on library/research orientations in their curricula are to be applauded for giving the student an appreciation of the literature.

Dr. Burch is incorrect, however, in thinking that Medline "retrieves publications of only the past 5 years or so"—the Medline data base includes citations from 1966 to the present.

Reply

To the Editor:

We thank Ms. Bury and Mr. Jones for their letter. On checking with our librarian, we were informed that Medline has two types of services. The "current" Medline extends back three years, but service may be obtained as far back as 1966. It must be remembered, however, that many important contributions have been made prior to 1966. Unfortunately, a review of the literature beyond 1966 is very time consuming.

Migration of redundant pacing electrode

To the Editor:

Retting and associates recently described a case of migration of a redundant transvenous pacing electrode (AM HEART J 98:587, 1979). In their case the electrode settled in the pulmonary artery and was retrieved via a thoracotomy.

We have had a similar experience but with a more serious consequence. The patient, a 74-year-old man, required permanent pacing because of Stokes-Adams attacks due to complete

Association for Advancement of Behavior Therapy

The 14th annual convention of the Association for Advancement of Behavior Therapy will be held on November 20 through 23 1980 at the New York Hilton New York City Included will be five sections of the 8 hour basic course in Clinical Behavior Therapy 12 pre convention institutes lasting 5 hours and limited to 30 participants and 40 workshops lasting 3 hours and limited to 125 attendees In addition there will be symposia panel discussions invited addresses and poster board sessions all presented by experienced professionals in the field

Book reviews

Interpreting the Electrocardiogram By James S Fleming New York 19 9 Update Publishing International Inc 13 pages.

This is an atlas type book designed to teach physicians how to interpret electrocardiograms The technic used is to teach the student how to interpret patterns i e by memorizing patterns without much knowledge of the fundamental of electrocardiography The fundamental aspects of electrocardiology and electrophysiology are not discussed The book is presented in such a manner that the reader need not have a knowledge of membrane potentials or the electric activation of the myocardium or the phenomenon of recession This book should prove useful to nurses and paramedical personnel who wish to have a practical knowledge of the patterns of electrocardiography The diagrams are many and simple and the tracings are well chosen

Cardiovascular Physiology III Volume 18 Edited by A C Guyton and D B Young Baltimore 19 9 University Park Press 368 pages Price $34.95

This is another excellent issue of *International Review of Physiology* which is concerned with cardiovascular physiology The contributors have condensed for the reader the new things of interest in the field of cardiovascular physiology The selected eight sections include contraction and relaxation of the myocardium determinants of systemic blood flow reflex control of vascular capacitance and skeletal muscle circulation transcapillary transport of small solutes and water interstitial lymphatic flow system pulmonary transcapillary exchange and pulmonary edema and cardiogenic hypertension The more recent publications of data are well oriented with physiologic studies repeated in the more remote past Anyone involved in cardiovascular physiology and training and teaching of clinical cardiovascular problems will find this publication to be a stimulating and thought provoking source of important material This review is quite different from most annual reviews in any field of medicine in that the reports are presented as an organized review of the respective subjects The editors and contributors have produced a valuable publication

Coronary Heart Disease Third International Symposium Frankfurt Edited by Martin Kaltenbach M D Paul Lichtlen M D Raphael Balcon M D and Wolf Dirk Bussman M D Acton Mass 1978 PSG Publishing Company 346 pages Price $47 00

This report on coronary heart disease includes the presentation and discussion at the Third International Symposium held in Frankfurt during February 19 8 The many short papers are divided into eight parts Part 1 related to coronary collaterals is of particular interest not only to physiologists and anatomists but to clinicians as well The importance of the collateral circulation in ischemic heart disease is nicely presented. Part 5 is devoted to discussion of coronary spasm a subject known to be important in cardiology for many years, but of considerable interest in clinical research at present The clinical importance of coronary spasm is well discussed by investigators directly interested in the problem Part 7 is devoted to the mechanical treatment of ischemic disease This part should interest all physicians who treat ischemic heart disease The entire publication is of considerable interest and value This book is highly recommended It is easy to read the illustrations and tables are good and the discussions are of interest to anyone who manages patients with coronary artery disease This is an excellent book that can best be appreciated by critical reading and study

Ambulatory Electrocardiography By Edward K Chung New York 19 9 Springer Verlag 241 pages Price $24 90

This book is intended for training in the use of Holter monitoring in the management of cardiac disease Chung has briefly outlined the indications, applications in diagnosis, interpretation record or protocol keeping by the patient and clinical problems for which it is most useful These discussions are followed by 100 case histories and segments of recordings with interpretations The book is primarily an atlas for beginners to learn how to employ Holter monitoring in the practice of cardiology This is a good book with its primary purpose achieved The reader who is not acquainted with this procedure will find the 100 case examples interesting and challenging even to cardiologists It is not possible to critically review each case presented This must be left to the readers Nevertheless Case 36 page 8 of a supraventricular tachycardia has two questions presented by the author to his readers One is "What is the treatment of choice?" How can this question be answered without the entire clincial data Cases like this do challenge a thoughtful critical reader This is a good book which should interest beginners as a supplement to other literature on cardiac arrhythmias

Myocardial Infarction second edition By Ary Louis Goldberger St Louis 1979 The C V Mosby Company 2? pages. Price $26 50

The second edition attests to the success of the first edition. The author has added new information to assist the clinician in continuing his training in electrocardiography with emphasis on the ECG diagnostic manifestations of myocardial infarction The author is the son of Dr Emanuel Goldberger who introduced the augmented limb leads to clinical electrocardiography The book is divided into two parts part one is concerned with depolarization (Q wave) pattern simulating myocardial infarction and part two is concerned with repolarization (ST T) patterns simulating myocardial infarction It is a good book which clearly presents the problems in differential diagnosis of myocardial infarction by ECG Physicians in training will find a critical study of this book to be a valuable effort The ECG remains of paramount importance in clinical cardiology Goldberger has selected good illustrations and included a good bibliography of 6 4 well selected references Myocardial infarction is an important and common problem in the practice of medicine and the ECG is of routine use in diagnosis and management This is a good addition to the medical literature

leisure to pursue full time academic and scholarly activities Scholarship has lessened because clinical duties are too time consuming and demanding Teaching suffers and the fundamentals of medical science and the depth of critical discussions self criticism and self evaluation are at a minimum In spite of large clinics and large hospitals and capable physicians outside the schools the medical schools are in private practice and in competition with the private practitioners and private clinics bearing the burden of large budgetary problems and ever demanding large salaries of the clinical faculty and private patient care This should not be

Thus with critical review it becomes evident that we have reverted back to 1910 in medical education How did this happen? Is it good? Where are the certifying groups who review full time medical schools? Why isn t medical education being critically reviewed in 1980 with scholarship and teaching and research being made the premium for dedicated scholars and scientists in medical schools people with missionary dedication to scholarly pursuits?

Outstanding teaching and training of physicians can be done only with strictly full time clinical faculty dedicated to scholarship teaching and research—a faculty willing to accept a financial sacrifice in exchange for opportunities to study think teach and do research on a full time basis without an excessive burden of primary patient service responsibilities Sufficient people exist in medicine to provide such a faculty for all medical schools of America In 1910 a change to full time faculty developed with success This can also occur in 1980 if the various administrations in the U S and the American people wish and are willing to bear the financial burden involved

Many more medical schools with small classes and highly motivated truly full time faculties must be the objective of medical education in America for the immediate future We need at least 300 more medical schools with small st de bodies and with excellent teachers in which t objective is to provide the best medicine for t people of America and in which earning mone not paramount The scholars of medical scho students and faculty should be expected to spe money and must not be concerned with earn money They must be concerned with trainin administering to the sick emphasizing preven medicine regardless of economic or social sta of the patients The people of America will be t winner in the end and therefore the people mu provide the support without restrictions—but, n by direct or indirect payment for services (fee f service) to a so called full time clinical facult The American people will benefit from th support through the improved services of bet trained graduates who eventually enter priva practice and become the full time private ph sicians of the people It takes time to teach and advance knowledge and it takes time to practi good medicine and care for the sick When the two types of medical endeavors are attemp simultaneously by the same people both usual suffer from poor performance and certainly suf from inadequate time for thought scholarsh teaching and learning

Let us re-emerge in 1980 as we emerged in 19 with true and strictly full time clinical facult and medical schools of scholars—faculties a students interested only in learning studen thinking and venture research Let the phy cians in private practice care for the sick on fee for service basis A volunteer faculty sho exist but a strictly full time faculty dedicated t scholarship teaching and research should consti tute the core of the medical schools

Editorials

Of 1910

George E Burch M D
New Orleans La

The Flexner report[1] appeared in 1910 marking the beginning of significant improvement in medical education in the U S A In 1910 there were many poor medical schools in which earning money was an important objective of the clinicians who owned the schools and controlled the hospitals Preclinical faculty was hired by these clinicians The faculties were not considered full time since they practiced private medicine to earn money for themselves Scholarship science and research and investigation into the unknown were essentially non existent Students who paid their tuition were essentially assured a diploma The Flexner committee exposed the inadequate medical education and recommended drastic changes especially the need for full time clinical faculty that would be concerned with teaching research and scholarship and not with the private practice of medicine In fact the full time faculty was definitely not to practice medicine privately The faculty was to teach good medicine and to search into the unknown through research thought and discourse for the sake of advancing knowledge The strictly full time clinical faculty was to produce outstanding physicians to render care of the sick with concern for the sick according to performance background and model established by the full time clinical teachers dedicated to scholarship The full time clinical faculties were rapidly instituted after the Flexner report was published The medical schools displayed pride and extreme satisfaction with their full time clinical faculty and their accomplishments The level of academic performance and rating of each medical school were determined by size and quality of the strictly full time faculty with reward for the best clinical scholars Any clinical faculty appointee with patient service responsibility and fee for service no matter how arranged was considered a part time and not a full time faculty member Even geographic full time appointment was not permitted at the outset Those who were interested in private practice joined the part time clinical faculty and made important contributions to their respective medical schools

We are now in 1980 but back to the level of 1910 in medical education We have been there for several years a transition which started 20 or more years ago The earning of money is now a strong motivation and an overly emphasized objective and concern of teaching medical institutions At present the universities and medical centers own the faculty the hospitals and the clinics The size of the hospital number of patients and funds earned seem to reflect important qualities of achievement—the same qualities which are considered a great achievement in private non academic clinics Budgets must be met and the magnitude of salaries is the index of success and faculty satisfaction The clinical faculties are now busy practicing medicine to earn money for the medical schools so the schools can meet these budgets and pay salaries including their own The faculties no longer are free and at

the epicardial and body surface ECG could be demonstrated which invalidated the earlier conclusions Durrer and associates[9] reported that even an SEI of extremely small size (1 cm in diameter) can lead to abnormal Q waves The 1957 report from Prinzmetal's laboratory and Durrer's studies are in full agreement with practically all later autopsy reports on the ECG in SEI Abnormal Q waves can be found in most SEI and TMI cases but they may be absent in a substantial number of infarcts of both types

Scher[1] has been one of the few investigators who took notice of the changing concepts in Prinzmetal's laboratory In his excellent review on the Excitation of the Heart in 1962 he stated The work of Prinzmetal and his colleagues deserves some comment All of the early papers in a very large series stressed the fact that most of the inner layers of the wall were silent and were depolarized before the beginning of the peripheral electrocardiogram A final paper in the series re-examined the major claim (excitation of inner layers before the beginning of QRS) and found it to be incorrect It appears truly amazing that in the relatively short interval of three years between the first and second report from Prinzmetal's laboratory an erroneous concept could become so deeply ingrained in cardiologists thinking

At this point in time one is tempted to conclude that no matter how many additional autopsy studies refuting the concept of the silent SEI will be published in the next decades the public at large will probably take little or no notice We have no ready explanation for the persistence of this concept which could have been abandoned in the late fifties It may be related to the shifting emphasis toward many other investigative procedures such as coronary angiography ventriculography and others and away from postmortem studies which used to be and still remain the most essential objective evidence for the presence or absence of infarction The fact remains that both TMI and SEI can be found in substantial numbers without typical Q wave abnormalities The electrocardiogram alone seems to be of little help in the differentiation between these two types of infarct

Many reasons have been given for the absence of Q wave abnormalities in certain patients with MI The presence of multiple infarcts MI location in certain regions of the left ventricle which are relatively silent [11] and changes lim the middle or late part of the QRS are o explanations which have been offered detailed discussion goes beyond the scope o editorial

Differentiation between TMI and SEI only of academic interest because it was fe some investigators that there might be a d ence in the clinical course and prognos patients having SEI or TMI Cases with SEI believed to have a more benign course Com sons were made, therefore between th patients with QRS abnormalities and others ST T changes only [13, 14] No autopsy confirm on infarct size and extension within the ventricular wall was available From the ea discussion it should have become clear that th patients could have had TMI or SEI To ou surprise no significant differences in the clin course and prognosis could be found

It is not inconceivable that patients subendocardial lesions might have a better p nosis than those with TMI With present ele cardiographic techniques a differentiation tween SEI and TMI does not appear feas However in addition to the relative loca within the left ventricular wall for prognosis has also to consider the total muscle mass wh has become necrotic Many subendocar infarcts are very large and almost circula ring like and the total amount of dead tissue these cases is substantial [15] More detailed corre tions between enzyme levels and ECG ch might lead to better clues for estimating infa size

"Silent" subendocardial infarcts fact or fiction?

Hubert V Pipberger M D
Emigdio A Lopez M D
Washington D C

During the last 25 years it has become customary to make a distinction between electrocardiograms which are considered compatible with subendocardial infarcts (SEI) and transmural infarcts (TMI) The former are believed to lead only to ST and T wave changes whereas QRS changes and more specifically the development of abnormal Q waves are considered characteristic for TMI According to this concept the subendocardium is electrocardiographically silent as far as the QRS complex is concerned

The vast majority of autopsy correlations reported in the literature are in disagreement with this simplistic concept In most recent years Savage and associates Sullivan and colleagues and Raunio and co workers reported in great detail on a total of 154 autopsies and their ECG findings prior to the patients death There appears to be general agreement between these investigators that the majority of cases with SEI exhibit typical QRS changes and furthermore that in a substantial number of patients with TMI the characteristic Q wave changes cannot be found Raunio and co workers[3] reported only very recently in the August 1979 issue of THIS JOURNAL on a new series of 80 autopsies In this very carefully executed study 53% of the SEI cases showed QRS changes which were typical for myocardial infarct (MI) Similar QRS changes were present in 65% of the TMI patients a difference which is hardly significant

Savage and associates[1] found 11 SEI cases in their autopsy series of 24 Ten out of these or 91% could be diagnosed as infarct on the basis of typical QRS changes and only one case with a posterior SEI had no abnormal Q waves in Leads II III or a V_F Abbott and Scheinman reported on 230 patients with acute MI In 78 or 34% of these cases the electrocardiogram did not show signs which are considered diagnostic for MI Eight cases of the latter group came to autopsy and all of them were found to have TMI

The literature on ECG findings in autopsy proven SEI and TMI cases has been reviewed recently very extensively by Savage and colleagues[1] and by Raunio and co workers[3] The history goes back to Wilson and associates who described typical Q wave changes with SEI both in animals and in men[4] There appears to be overwhelming evidence that most SEI cases show Q wave abnormalities which are typical for MI Furthermore the percentage of SEI cases which do not exhibit characteristic Q wave changes appears to be very similar to that of TMI cases without Q wave abnormalities To distinguish between SEI and TMI on the basis of the electrocardiogram seems therefore not possible

How then did the ECG differentiation between these two types of infarcts develop? The work which is most often quoted is that of Prinzmetal and associates[5] who reported in 1954 on experiments in seven dogs with chronic SEI and on twelve dogs with acute SEI From their results they concluded that subendocardial depolarization is silent and thus should not affect the electrocardiogram In a later study from Prinzmetal's laboratory in 1957 when more refined recording techniques had become available a significant contribution of the subendocardium to

Evaluation of contractile state of the left ventricle from the peak of the first derivative of the apexcardiogram

Nikolai S Kolev, M D
Varna Bulgaria

Johnston and Overy[1] were the first to report that the magnitude of the first derivative of the apex cardiogram (dA/dt) was in close relation to the contractile state of the myocardium Some authors [*] using suitable mechanical calibrating devices determined left ventricular wall velocity and other quantitative indexes from the height of dA/dt Because of the difference among individual subjects in cardiac size and body build, quantitation of left ventricular wall velocity has not been feasible by this method [7, 8]

Reale proposed an alternative approach of using the first derivative of the apexcardiogram He established the similarity between the interval from the onset of ventricular depolarization and the peak of the first derivative of the apexcardiogram on one hand and the interval from the R wave of the electrocardiogram to the peak dP/dt, on the other hand as suggested by Mason and colleagues [1]

In order to maintain the informative value of the height of the peak dA/dt and avoid the calibrating difficulties we proposed a new way of interpreting the peak dA/dt The amplitude of the peak dA/dt was expressed as a percent of the total deflection of the first derivative of the apexcardiogram

The present study was designed to assess the clinical value of measuring the peak of the first derivative of the apexcardiogram (1) by defining the normal values of the ratio of peak dA/dt a[illegible] the duration of the interval from ventric[illegible] depolarization to peak dA/dt (R to peak dA dt) (2) by investigating the effect of different pha[illegible] macologically induced variations in the contra[illegible] tile state of the human myocardium on the abo[illegible] parameters and (3) by comparing patients w[illegible] impaired left ventricular function with contro[illegible]

Subjects and methods

A left apexcardiogram and its first deri[illegible] were obtained in 104 individuals—50 normal su[illegible] jects ranging in age from 20 to 61 years (mean a[illegible] 38 ± 14 years) and 38 patients with ischem[illegible] heart disease ranging in age from 35 to 73 ye[illegible] (mean age 51 ± 16 years) In 16 additional su[illegible] jects the effect of pharmacological agents w[illegible] positive and negative inotropic action was st[illegible] ied

In the group of normal subjects no presen[illegible] history of heart disease was presented and [illegible] complete physical examination 12 lead electro[illegible] cardiogram, carotid pulse tracing apexcard[illegible] gram and chest x ray were normal

The patients with ischemic heart disease had [illegible] history of old myocardial infarction—6 month[illegible] 12 years after onset Their diagnosis was based [illegible] typical anamnestic data, electrocardiograph[illegible] examinations and increased enzyme activ[illegible] the acute phase When investigations were pe[illegible] formed all patients suffered from decompensated coronary artery disease (degree of decompensa[illegible] tion Class I to II according to the criteria of the New York Heart Association) Not included [illegible] the study were the patients on digitalis [illegible] antiarrhythmic agents and patients with bu[illegible] block

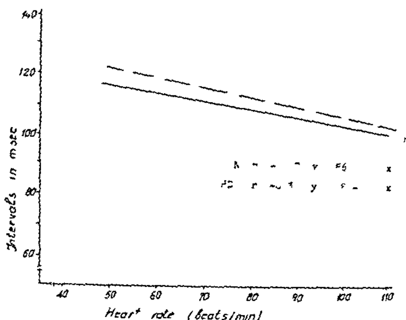

Fig 2 Linear regression analysis between interval R to peak dA/dt and resting heart rate in normal subjects (N) and in patients with ischemic heart disease (IHD)

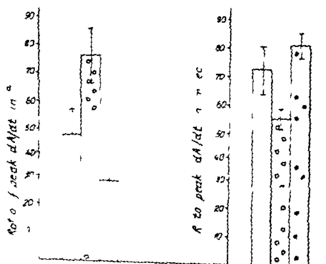

Fig 3 Mean changes in the average values of ratio of peak to total amplitude (dA dt) (left) and interval R to peak dA/dt (right) at rest (plain bar) after beta adrenergic stimulation (bar with open circles) and after beta adrenergic blockade (bar with solid circles) Each bar represents the mean ± SD

−29 ± 15 (p < 0 001) and the interval R to peak dA/dt was increased by 9 ± 6 msec (p < 0 02) (Figs 3 and 4)

In the patients with ischemic heart disease a decrease of the ratio of the peak dA/dt occurred and its mean value amounted to 32 ± 13% (p < 0 001) In the same patients an elongation of the interval R to peak dA/dt with a mean value 121 ± 15 msec (p < 0 01) was also found

Discussion

Although the exact genesis of the apexcardiogram is not clearly understood many observations indicate that the configuration the time course the height and the slope (especially in the isometric phase) of the apexcardiogram are significantly correlated with left ventricular pressure[3,4] Reale[7] reported the similarity in time and contour between the first derivative of the left ventricular pressure and the first derivative of the apexcardiogram It was shown in experimental studies[3,4] and clinically[5] that correlation between the first derivative of the apexcardiogram and left ventricular pressure during hemodynamic changes was fairly good All the authors used a calibrating device when determining the height of the first derivative of the apexcardiogram and expressed its value in different units—mm Hg/sec[3,4] X/sec[5] or g/sec[6]

Quantitation of peak dA/dt by use of the absolute value of amplitude have been [illegible] because of differences among individual subjects in cardiac size and thoracic shape[3,4] Owing to the difficulties in calibrating the sensing device and therefore in assessing units of measurement of the first derivative of the apexcardiogram we examined the relative height of the peak of dA/dt as percent of the total amplitude of the first derivative

Our data for parallel modifications of the ratio of peak dA/dt after pharmacologically and [illegible]

Pharmacological interventions were performed in 16 volunteers in order to study the effect of positive and negative inotropic drugs on the first derivative of the apexcardiogram Isoprenaline infused intravenously at a rate of 0 003 μg/kg/minute and propranolol (Obsidan GDR) 5 mg intravenously were given in order to obtain the appropriate effect Informed consent was obtained from the subjects prior to the examination

The polygraphic tracing was performed by rotating recumbent subjects 30 to 50 degrees toward the left lateral decubitus position Apex cardiograms were recorded by means of a piezo electric transducer (RFT GDR) with an infinite time constant The transducer was held by a circumferential adhesive strap at the point of *maximal impulse of the apex beat of the heart*

The first derivative of the apexcardiogram was obtained by passing the pulse wave of the apex cardiogram through a resistance capacitance (RC) network differentiator The differentiator was constructed in our laboratory and consists of a low pass filter followed by a high pass filter both filters having the same time constant (0 1 msec) with a flat response in a range of 0 to 80 Hz The attenuation of the differentiator is down 20 db per decade Thus high frequencies are accentuated and low frequencies are attenuated

During mild expiratory apnea simultaneous records were made of the electrocardiogram phonocardiogram apexcardiogram and dA/dt on a six channel recorder (6 NEK 3 GDR) Paper speed was 100 mm/sec

Analysis of the simultaneous tracings (Fig 1)

1 Ratio of positive amplitude to total amplitude of the first derivative of the apexcardiogram expressed as a percent of total deflection

2 Interval from R of the electrocardiogram to the peak of the first derivative of the apexcardiogram (R to peak dA/dt) This interval was corrected for heart rate by formulas from regression analysis in Fig 2 which represents the relation between heart rate and survival R to peak dA/dt in normals and in patients with ischemic heart disease

Results

In the control group the mean ratio of the height of the peak dA/dt was 48 ± 14% of the total deflection of the first derivative of the apexcardiogram The interval from R of the electrocardiogram to the peak of the dA/dt was 73 ± 15 msec

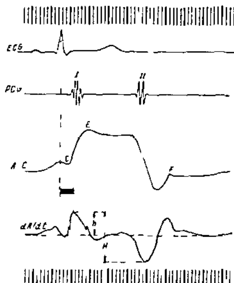

Fig 1 Simultaneous recordings of electrocardiogram *(ECG)* phonocardiogram *(PCG)* apexcardiogram *(ACG)* and first derivative of apexcardiogram *(dA/dt)* *Blackened area* denotes the interval from R wave of ECG to peak dA/dt *h* denotes the peak amplitude of dA/dt and *H* represents the total amplitude of dA/dt *The vertical lines* determined 0 02 sec intervals

To evaluate the possible influence of resting heart rate on interval R to peak dA/dt a linear regression analysis of the first variable with the latter was carried out in the 56 normal subjects and in 38 patients with ischemic heart disease There was some tendency of interval R to peak dA/dt to decrease at increasing resting heart rate (Fig 2) however the inverse correlation was very slight although significant (normal subjects $r = -0\ 37$ $p < 0\ 01$ ischemic heart disease $r = -0\ 39$ $p < 0\ 01$)

Sixteen young adult men with no cardiac disease submitted to intravenous injection of isoprenaline The ratio of peak to total amplitude (dA/dt) showed augmentation and its mean value amounted to 81 ± 16% whereas the mean basal value was 49 ± 15% ($p < 0\ 001$) moreover the interval R to peak dA/dt was reduced by −16 ± 5 msec ($p < 0\ 001$) *In the same subgroup a deter*mination repeated after the infusion was stopped showed parallel returns of the above parameters toward perfusion levels Following beta adrenergic blockade with propranolol the mean ratio of peak to total amplitude was diminished to

Summary

Simultaneous records of the electrocardiogram, phonocardiogram apexcardiogram (ACG), and the first derivative of the apexcardiogram (dA/dt) were obtained in 50 normal subjects and in 38 patients with ischemic heart disease This allowed us to measure the ratio of peak dA/dt to total amplitude of the first derivative in percent and the interval from electrical stimulation to peak dA/dt (R to peak dA/dt) In 16 additional normal subjects the effects of pharmacological agents with positive and negative inotropic action were studied with the above parameters During isoprenaline infusion the ratio of peak to total amplitude dA/dt was increased and the interval R to peak dA/dt was shortened, while after propranolol the ratio of peak dA/dt diminished and the interval R to peak dA/dt showed elongation

In normal subjects the ratio of peak dA/dt averaged 48 ± 14% and it is significantly lower in patients with ischemic heart disease (32 ± 13%, $p < 0.001$) In controls the interval R to peak dA/dt was 73 ± 15 msec whereas in ischemic heart disease it showed elongation (121 ± 15 msec $p < 0.01$)

It is concluded that the ratio peak dA/dt and the interval R to peak dA/dt expressing noninvasively the rate of pressure changes and the duration of the development of maximum tension during isovolumic contraction provide useful information on left ventricular function

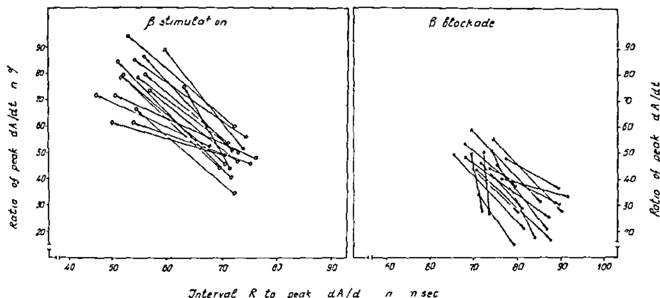

Fig 4 Variations of the ratio of the peak of the first derivative of the apexcardiogram to total derivative expressed as a percent and interval R to peak dA/dt expressed in msec during isoprenaline infusion and after propranolol *The arrows* point to values obtained after pharmacological intervention There is a strong reciprocal correlation between changes in the height of the peak dA/dt and the interval R to peak dA/dt The near parallelism of the curves indicates similar rates of change for both factors in all patients.

variation in the contractile state was confirmed with similar methods Mason and colleagues found that when the myocardial contractile state was enhanced by orciprenaline infusion there was an evaluation of peak dp/dt Conversely when contractility was depressed by beta adrenergic blockade most patients showed a lower peak dp/dt

The precise experiments in dogs by Willems and colleagues[3] during the effects of different interventions established the changes in amplitude of the calibrated dA/dt expressed as a percent of the controls They found a 60% elevation of the dA/dt provoked by isoprenaline and a decrease by 40% after propranolol Denef and associates[4] reported that in dogs positive inotropic interventions provoked a marked increase in peak dA/dt whereas negative inotropic agents had the opposite effect furthermore they found a fairly good correlation between these changes and changes of left ventricular dp/dt after the same pharmacological interventions Similar results were obtained clinically[5]

Mason and co workers measured the interval from electrical stimulation to peak dp/dt and assumed that it expressed the duration of the development of maximal tension in the ventricle They found that the same interval was inversely related to the contractile state in the isolated muscle strip and also that it was independent of preload and afterload Several authors[5, 7, 8] investigated the interval from the onset of ventricular depolarization to the peak of the first derivative of the apexcardiogram and found that the interval R to peak dA/dt has the same significance as the interval R to peak dp/dt It has been demonstrated that the interval R to peak dA/dt increased after beta adrenergic blockade[7] and shortened when the patient was given a beta adrenergic agonist[5, 7, 11] Other authors established an elongation of the same interval in patients with left ventricular failure due to atherosclerotic coronary heart disease and a close correlation between the interval R to peak dA/dt and the ejection fraction[8]

In conclusion our findings relative to changes of the interval R to peak dA/dt are in agreement with the investigations of several authors[5, 8] The proposed ratio of peak dA/dt to total amplitude of the derivative avoid the difficulties in calibrating the apexcardiogram and its first time derivative and simultaneously using the ratio of peak dA/dt and interval R to peak dA/dt permits a more complete noninvasive evaluation of the contractile state of the left ventricle from the peak dA/dt

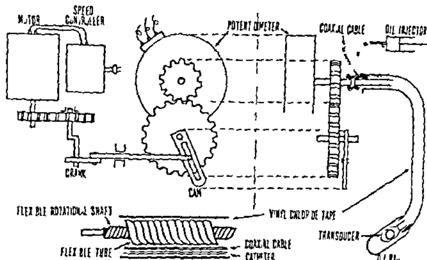

Fig 1 Diagrammatic illustration of the transesophageal sector scanner A small transducer in the esophagus is alternately rotated by a flexible rotational shaft and motor at 6 to 25 Hz (12 to 50 fields/sec) Although the small transducer is rotated alternately with great speed, there is little movement of the external flexible tube or oil bag, minimizing irritation or trauma to the esophagus

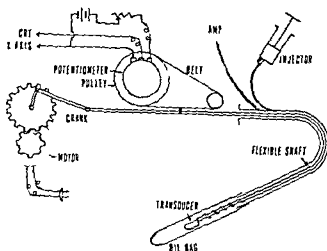

Fig 2 Diagrammatic illustration of the transesophageal linear scanner A small transducer in the esophagus is moved up and down by the flexible shaft and motor at 4 to 10 Hz (8 to 20 fields/sec)

continuously by phase control of alternating voltage using thyristors Maximum selective pulse repetition frequency is 6 0 KHz The field of view varies in depth from 10 cm to 17 cm according to the pulse repetition frequency The sector angle varies from 60 degrees to 180 degrees by changing a connecting point of a cam (Fig 1) Thus horizontal images of the entire adult heart can be obtained with this scanner Although the transducer is rotated at a high frequency the external flexible tube is stable within the esophagus Moreover the enveloping oil bag minimizes trauma to the esophagus (Fig 1) To identify the echo source of the cross sectional image a particular scan line is manually selected and B mode is switched to M mode to obtain M mode esophageal echograms

Linear scanner In order to obtain vertical images of the heart a transesophageal mechanical linear scanner was developed Fig 2 shows a diagram of the linear scanner A small transducer (transducer specifications as in the transesophageal sector scanner) is moved up and down in the esophagus by a flexible shaft and a motor at a rate of 4 to 10 Hz The plane of the scan is vertical through the center of the esophagus As shown in Fig 2 a potentiometer is rotated simultaneously with the transducer and monitors its position The signals detected by the transducer are amplified and displayed on a CRT as B-mode so that the position of an individual scan line corresponds exactly to the position of the transducer at the same instant Thus vertical cross sectional heart images are displayed in rectangular format on a CRT at a rate of 8 to 20 fields/sec The movement of the transducer can be varied from 2 5 cm to 8 cm by changing the crank Pulse repetition frequency and depth of field are as in the sector scanner

Recording methods A Polaroid camera, 35 mm still camera 8 mm movie camera and 16 mm movie camera can be utilized for the recording

Transesophageal cross-sectional echocardiography

Kohzoh Hisanaga M D
Asako Hisanaga B S
Kazuhiko Nagata M D
Yoshiyasu Ichie, M D
Nagoya Japan

Real time cross sectional echocardiography has proven useful for diagnosis of certain cardiac diseases and several imaging systems have been developed[1-7] However because the heart is observed through a small echo window on the chest wall the area which can be observed is considerably restricted In addition it is sometimes difficult to obtain heart images of diagnostic quality in patients with chronic obstructive pulmonary diseases barrel chest and obesity In order to minimize these limitations and to observe a wider area of the heart we developed a transesophageal high speed scanning system which can obtain cross sectional heart images without hindrance from ribs sternum and lung

Methods

The scanning system employs two kinds of hand held mechanical scanners each having a flexible tube and small ultrasonic transducer contained within a small oil bag which allows easy swallowing by adults One is a sector scanner which obtains horizontal images of the heart and the other is a linear scanner which obtains vertical images of the heart These scanners are used in conjunction with an improved Toshiba SSL 51H system which was originally developed as a transchest wall mechanical sector scanner

Sector scanner The sector scanner consists of a motor (single phase commutator type) which can control the speed of rotation an iron flexible tube containing a flexible rotational shaft and a small transducer which is enclosed in an oil bag (15 mm diameter) (Fig 1) The specifications of the transducer are 2.25 MHz or 3 5 MHz 10 mm diameter and 7 5 cm focus The transducer is mounted in a 12 mm by 20 mm by 6 mm casing with rounded edges for easy esophageal passage, and is positioned at the tip of the flexible rotational shaft The flexible rotational shaft is enclosed in the iron flexible tube which has a diameter of approximately 8 mm and the latter is then wrapped with vinyl chloride tape The patients can easily swallow the flexible tube and shaft The oil bag which covers the transducer can be filled with oil by means of an injector The small transducer in the esophagus is rotated alternately by the flexible rotational shaft and the motor at a rate of 6 to 25 Hz The ultrasonic beam is alternately swept to the left and to the right so that the plane of the scan is perpendicular to the esophagus and the resultant images are displayed in a circular format The position of the transducer in the esophagus is continuously detected by a potentiometer which is connected directly to the flexible rotational shaft The signals of reflected echoes are displayed on a cathode ray tube (CRT) as B mode so that the angle of an individual scanning line is equal to the angle of the transducer at the same instant In this way horizontal cross sectional heart images are displayed on a CRT at a rate of 12 to 50 fields/sec Since a single phase commutator motor is employed the motor speed can be varied

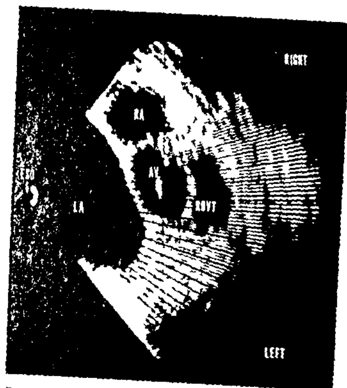

Fig 4 Horizontal scan at the level of the aortic valve as in Fig 3 The aortic cusps are closed in diastole Large left atrium is seen Right ventricular outflow tract is seen anterior to the aorta AV = aortic valve RVOT = right ventricular outflow tract

Fig 5 Transesophageal vertical linear scan through the pulmonary artery in another normal subject Bifurcation of pulmonary artery and part of ascending aorta are seen AO = aorta PA = pulmonary artery BI = bifurcation of pulmonary artery

utilize a transducer of higher frequency increasing resolution of heart images remarkably Unlike conventional external echocardiograms this system can continuously record heart images from the base to the apex as the transducer is being withdrawn or advanced in the esophagus Furthermore because of the wider sector angle entire horizontal heart images can be easily observed at the level of the atrioventricular valves The bifurcation of the pulmonary artery could be readily observed during vertical scanning However the area above the bifurcation of the pulmonary artery could not be seen because of interference from the trachea In addition it is easier to obtain M mode esophageal echograms while locating the various cardiac structures utilizing B mode echocardiography

We have found that the insertion of the transducer for recording heart images through the esophagus is no more difficult than inserting a commercially available gastrofiberscope The small flexible tube and transducer are easily swallowed and occasional gagging is usually so mild that the examination is hardly interrupted Although the transducer is moved rapidly there is no loss of esophageal wall contact nor is there esophageal trauma since the oil bag covers the transducer

Limitations of the described system include (1) fewer scanning planes (horizontal and vertical) available in comparison with conventional surface methods and (2) bubbles which may reduce image resolution occasionally form in the oil bag during linear scanning However current modifications and developments are devoted to overcoming these limitations[11]

In conclusion transesophageal cross sectional echocardiographic examination can be performed safely and the described system provides high resolution echoes of major cardiac structures in both horizontal and vertical scans There is little difference in the image quality among such scans Although this method is in an early stage of development we believe that in the future tran-

uated in 31 adult subjects (average age 36 4 years range 20 to 73 years average height 165 2 cm average body weight 58 7 kilograms) Prior to examination the patients usually received 0 5 mg of atropine sulfate and 10 mg diazepam intra muscularly and 3 g of lidocaine jelly orally The patients throats were sprayed with 4% lidocaine liquid Lidocaine jelly was applied to the oil bag and flexible tube in order to minimize discomfort and the loss of contact with the esophageal wall

Subjects usually swallowed the oil bag volun tarily and as easily as a commercially available esophageal fiberscope Oil was then injected into the bag through an external catheter in order to obtain good contact with the esophageal wall

Insertion of the transducer and transesopha geal ultrasound examinations were usually per formed with subjects in the left lateral or supine positions

Results

Following insertion to the 30 to 40 cm level good quality cross sectional heart images were observed in all 31 subjects All major cardiac structures were observed by withdrawing and advancing the transducer in the esophagus Com plete horizontal heart images were observed from the level of the atrioventricular valves (Fig 3) and the aortic valve (Fig 4) Vertical scanning demonstrated cardiac structures from the level of the aorta to the bifurcation of the pulmonary artery (Fig 5)

Discussion

Since B mode echocardiography has been applied to diagnosis of cardiac disease it has proven useful in anatomical and functional assessment of the heart and several real time imaging systems have been developed Bom and colleagues and King[3] have described multi trans ducer linear scanning systems which display heart images in a rectangular format whereas Griffith and Henry Eggleton and associates and Nishimura and co workers utilized mechan ical sector scanning of a single transducer to produce real time heart images On the other hand Somer and Von Ramm and Thurstone developed sector scanning systems to rely on phased array principles without the necessity of mechanical motion However thoracic configura tion excessive chest wall tissue or air containing

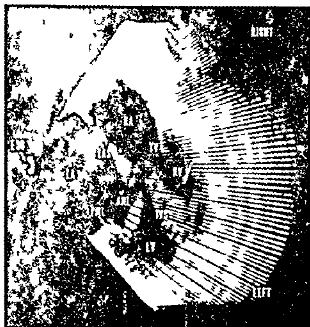

Fig 3 Transesopha eal horizontal sector scan during dias tole at the level of the mitral and tricuspid valves in a patient with severe mitral stenosis Tricuspid valve mitral valve ventricles and atria are seen Anterior and posterior mitral leaflets are thickened. *ESO* = esophagus *LA* = left atrium *RA* = right atrium *LV* = left ventricle *RV* = right ventri cle *IAS* = interatrial septum *IVS* = interventricular sep tum *AML* = anterior mitral leaflet *PML* = posterior mitral leaflet *TV* = tricuspid valve

lung may often limit the fields of view and resolution In order to minimize these limitations Frazin and colleagues have recorded M mode echocardiography through the esophagus using a small transducer which patients can swallow On the other hand Hisanaga and associates have developed a transesophageal pulsed Doppler echocardiographic system Although these meth ods are useful they do not provide two dimen sional cardiac images

We developed a transesophageal cardiac imag ing system which can obtain heart images with out hindrance from ribs sternum and lung Transesophageal echocardiography provides a wider area for study of the heart than that available using a conventional external system Heart images are observed through esophageal tissue in which ultrasound absorption is very low Therefore there is little difference in the image quality among various subjects In clinical exam inations one could obtain heart images with very low gain amplitude Thus one might potentially

Constituents of the human ventricular myocardium Connective tissue hyperplasia accompanying muscular hypertrophy

The ease with which blood enters and distends the cardiac ventricles during diastole is related to the compliance or stiffness of the ventricular wall When the wall is stiff a greater energy must be present in the entering blood to produce the same degree of ventricular filling as is produced by blood under lower pressure when the wall has normal compliance It is the pressure energy of this blood entering the ventricles that when pathologically elevated may lead to the signs and symptoms of congestive heart failure Thus decreased compliance of the ventricular wall may be a cause of congestive heart failure

The compliance stiffness or tensile stress resisting capacity of the myocardium probably reflects the summation of the mechanical properties of its constituent muscle and interstitial connective tissue Muscle cells themselves will vary in the deformity or strain produced by an applied stress that is their elasticity depends on their state of contraction When muscle is relaxed its compliance is high—i.e it extends readily under an applied tension[2] T

esophageal cross sectional echocardiography will be useful for cardiac diagnosis in the patient with nondiagnostic transthoracic echoes

Summary

A transesophageal cardiac imaging system is described This system employs hand held mechanical sector and linear scanners each having a flexible tube and a small ultrasonic transducer contained within a small oil bag easily swallowed by adults In the sector scanner a small transducer in the esophagus rotates alternately and horizontal heart images are displayed In the linear scanner a small transducer in the esophagus moves up and down and vertical heart images are displayed The system was evaluated in 31 adult subjects In all subjects stable high quality heart images were observed continuously from base to apex as the transducer was being withdrawn or advanced in the esophagus In horizontal scans entire heart images were observed at the level of the atrioventricular valves In vertical scans the bifurcation of the pulmonary artery could be observed clearly There was little difference in the image quality among subjects

method A grid with 36 intersection points in one 10 power ocular of a binocular microscope was positioned randomly over areas of the myocardial region being studied histologically and the type of tissue each point lay on was determined (Fig 1) Points which fell on empty spaces in the section created as artifacts of preparation were excluded Such points usually amounted to about 15% of the total Intersections falling on cardiac muscle cell sarcoplasm or nucleus were called muscle and all other points not on artifactual empty space were considered connective tissue Between three and six grid settings were evaluated for each area of myocardium using the 25 power objective lens The grid covered an area of 0 016 mm Areas to be counted were chosen by scanning the slide under low magnification within this area fields to be counted were randomly selected The reproducibility of the determinations in serial counts and in blind recounting of slides was excellent rarely greater than 10% difference between counts

The density of cardiac muscle cell nuclei was determined for each of the three areas of myocardium for which the percent of constituents had been determined Using the same ocular grid as above the number of cardiac muscle cell nuclei falling within the square were counted for a minimum of five randomly selected fields from right to left ventricular free wall and interventric ular septum Nuclei touching the upp margins of the grid were included tho the lower and right margins were exc reproducibility of counts on separate tions and the similarity of values o counts was excellent The counts expressed as nuclei per grid area (0 016 used for comparison only

In an effort to study the possib ischemia as the basis for alterations n nective tissue content of the ventricula dium diameter measurements were ma major epicardial coronary arteries In studies of these vessels it has been show cube of a parent vessel diameter appr equals the sum of cubes of the branc Thus in coronary arteries unaffected b sclerotic disease we can construct a theoretical single coronary artery wh eter cubed equals the sum of diameters the right and left coronary arteries In so the angiographic injection of the left m nary was unsatisfactory so this theoreti coronary artery was obtained from the diameters cubed of the right left ant scending and left circumflex coronaries.

Finally pairwise correlation coefficien son s r) were computed for all possible pa following 12 variables (1) age in years (weight in grams (3) body surface area in

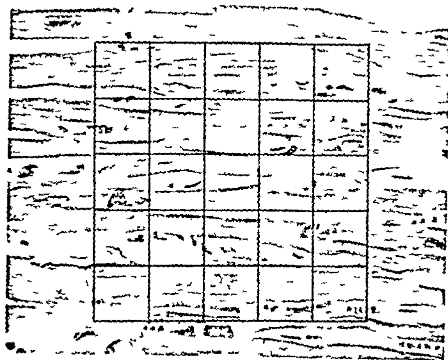

Fig 1 Left ventricular myocardium with superimposed ocular grid used for counting cardiac muscle cell nuclei and determining the myocardial constituents by point counting (Hematoxylin and eosin original magnification ×400)

gram revealed no vascular abnormality and gross examination of multiple transections of the epicardial coronary arteries showed at most only trivial atherosclerosis Cases with replacement fibrosis or amyloid infiltration that could interfere with the determinations were excluded

The coronary arteries were injected with a barium gelatin pigment mass at 100 to 150 mm Hg pressure The heart was then immersed in formalin and fixed in distention at 30 to 40 cm H_2O pressure by intracavitary formalin introduced through cannulae in the atria and great vessels After fixation stereoscopic radiographs were prepared of the intact heart and the transverse slices into which it was cut Multiple histological sections of the ventricular myocardium were prepared by routine processing sectioning and staining which at a minimum included left and right ventricular free wall and interventricular septum taken from transverse sections at the approximate level of the widest diameter of the left ventricle

Each case was assigned to a disease group based on the results of a previous analysis of the clinical and pathological features Normal applied to those cases with neither clinical nor pathological evidence of heart disease Cases designated LVH were those with left ventricular hypertrophy as the major finding usually secondary to aortic valve stenosis or systemic hypertension RVH categorized those cases with predominant right ventricular hypertrophy secondary to pulmonary hypertension as caused by mitral stenosis or pulmonary parenchymal disease Cases in the Chronic Dilatation group had left ventricular hypertrophy secondary to dilatation as for example with aortic or mitral regurgitation or idiopathic myocardiopathy Cases with features of more than one process were assigned to a group according to the predominant or primary abnormality The determination of the presence of congestive heart failure was made from the available clinical records of diagnoses of the clinicians caring for the patient during life

The gross and histological features of the ventricular walls were studied for each case The amount and distribution of interstitial connective tissue was noted for the free wall of right and left ventricle and septum for each heart The percent of myocardium in each of the three areas which consisted of muscle cell and of interstitial connective tissue was determined by a point count

Results

The major characteristics of the 127 patients with normal coronary arteries included in this study are shown by disease groups in Table I There were 33 normal hearts 28 hearts with left ventricular hypertrophy 25 hearts with right ventricular hypertrophy and 41 hearts with chronic dilatation The patients were all adults with comparable ages at death The normal hearts averaged 332 grams while the hearts with right ventricular hypertrophy left ventricular hypertrophy and chronic dilatation showed progressively larger abnormal weights None of the patients with normal hearts less than half with left and right ventricular hypertrophy and 90% of cases with chronic dilatation had a clinical history of congestive heart failure

The normal heart has a nuclear density (Table I) of about 1[illegible] per grid area in the interventricular septum and in both ventricular free walls but the larger diseased hearts namely those with left ventricular hypertrophy and chronic dilatation showed significantly decreased density of cardiac muscle nuclei (Student [illegible] t test) indicating that the cardiac mu[illegible] [illegible] increase in size rather than in number [illegible] contrast determinations of the percentage of [illegible] cell mass in relation to connective tissue [illegible] it remains relatively constant at 7[illegible]% of the myocardium in the thr[illegible] segments of the normal human ventricle and [illegible] not significantly altered in disease states wh[illegible] enlarge the heart

Pearson's r coefficient was calculated for [illegible] pairs of 12 measurements taken on each he[illegible] and is summarized in Table II Only r val[illegible] which were significant at the 0.01 level (Stud[illegible] t test) are displayed Wall thickness mea[illegible] ments correlated in parallel with heart wei[illegible] measurements and are not shown here We fo[illegible] that nuclear density in the three ver[illegible] segments is negatively related to heart wei[illegible] Other correlations in this table represent predi[illegible] able interrelationships of nuclear density or p[illegible] cent muscle to one another between the thr[illegible] different segments of the heart wall We have [illegible] explanation for the positive correlation betw[illegible] LV nuclear density and LV percent muscle [illegible] contrast heart weight is *not* correlated to perc[illegible] muscle in all three segments that is, $p > 0.0$[illegible] all three correlations We can summarize the[illegible] correlations by observing that as heart wei[illegible] increases myocardial muscle cell nuclear den[illegible] decreases showing that muscle hypertrophy occurs with cardiac enlargement By contrast the percentage of myocardium consisting of musc[illegible] does *not* change showing that commensura[illegible] connective tissue increase is a component of cardiac enlargement

In some hearts with dilatation and hyper[illegible] phy we observed a characteristic increase of connective tissue in the perivascular area [illegible] in Fig 2. This localized accentuation of co[illegible]

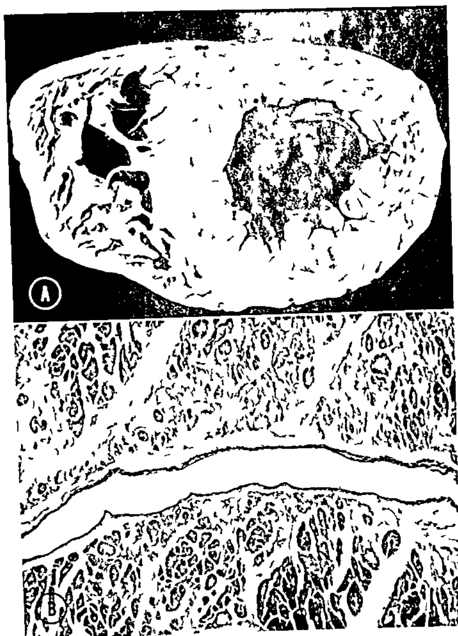

Fig 2 *A* Transverse section of the ventricles of a markedly enlarged heart with chronic dilatation. The left ventricular free wall myocardium on the right shows numerous striae of connective tissue running between the epicardium and endocardium. The striae are especially prominent in the mid part of the wall. *B* The striae are found to be an accumulation of interstitial connective tissue around blood vessels on histological examination. (Hematoxylin and eosin, original magnification ×75)

right ventricular free wall thickness in cm, (5) right ventricular free wall nuclear density per grid area, (6) right ventricular free wall percent muscle of myocardium, (7) interventricular septum thickness in cm, (8) interventricular septum nuclear density per grid area, (9) interventricular septum percent muscle of myocardium, (10) left ventricular free wall thickness in cm, (11) left ventricular free wall nuclear density per grid area, (12) left ventricular free wall percent muscle of myocardium. These correlation coefficients were used to identify the existence and direction (positive or negative correlation) of linear trends in the data. It is recognized that this calculation, which

shown by the distribution of the fibrosis *around* the larger intramyocardial arteries (expansive striae) and by correlations which suggest that the large epicardial coronary arteries increase in parallel with cardiac enlargement. Other workers have independently observed an increase in large coronary size with cardiac hypertrophy.

The evidence suggests that cardiac enlargement occurs by muscle cell hypertrophy and by maintenance of a uniform proportion of interstitial connective tissue. The decrease in compliance or increased stiffness associated with congestive heart failure may in some cases result from a simple increase in wall thickness of the myocardium.

Summary

Left sided congestive heart failure may be secondary to decreased left ventricular myocardial compliance in some patients. To investigate the anatomic basis for altered wall stiffness, morphometric determinations of muscle cell nuclear density and percent of myocardium consisting of muscle cells were made for right and left ventricular free wall and septum in 127 hearts with normal coronary arteries. The hearts were normal (33 patients), had left ventricular hypertrophy (28 patients), right ventricular hypertrophy (25 patients), or chronic dilatation (41 patients). With cardiac enlargement the average percent of myocardium consisting of muscle did not change from the approximately 75% value characteristic of normal hearts. In contrast, muscle cell nuclear density decreased proportionate to cardiac enlargement, demonstrating that muscle cell hypertrophy, not hyperplasia, is the basis for weight increase. Some hearts with marked long standing dilatation also had perivascular and interstitial striae of connective tissue differing from replacement fibrosis. An increase in epicardial coronary artery caliber commensurate with increased heart weight suggests that ischemia is not the basis of connective tissue increase. The results show that cardiac muscle cell hypertrophy is accompanied by commensurate increase in interstitial connective tissues. This pattern of myocardial growth with cardiac enlargement may produce increased myocardial stiffness simply as a result of increased wall thickness and may lead to left sided congestive heart failure.

tive tissue may contribute to increased stiffness of the myocardium in some hearts That these so called expansive striae are indeed part of the growth process in cardiac enlargement rather than fibrosis secondary to chronic ischemia is suggested first by their location namely in the distribution of nonatherosclerotic blood vessels which would least likely be ischemic The lack of an ischemic basis is further supported by correlations of coronary diameter and other variables measured in this study The diameter of the theoretical coronary is shown in Table III correlated to heart weight and wall thickness and nuclear density of the interventricular septum and left ventricular free wall These correlation values are all significant at the 0 01 level The most striking finding is the positive correlation between diameter of the theoretical coronary with heart weight This suggests that as the heart enlarges total coronary blood flow in these patients grows concurrently to accommodate the needs of the myocardium The increase of coronary flow with increased interventricular septum and left ventricular free wall thickness likewise suggests that the enlarged hearts in our series developed compensatory blood flow As previously demonstrated a decrease in the nuclear density parallels cardiac hypertrophy and likewise correlates with increased coronary flow All these correlations support the concept that the enlarged hearts in this series stimulate the necessary blood flow and do not develop increased connective tissue on the basis of ischemia

Table III Variables significantly correlated (Pearson s r) to the diameter of the theoretical coronary artery ($p < 0\ 01$)*

Variable	r

IVS = interventricular septum LV = left ventricle
*Nonsign ficant correlations at the 0 01 level are not displayed Results show that coron ry lum n size increases with increasin heart weight.

Discussion

Many patients with enlarged ventricles develop congestive heart failure One explanation for this congestive failure may be a decreased compliance of the ventricular myocardium In this study we examined 127 hearts from autopsied patients with normal coronary arteries and no destructive or infiltrative myocardial lesions About half the patients in the study carried a clinical diagnosis of congestive heart failure and had enlarged hearts at autopsy With cardiac enlargement cardiac muscle cells were found to increase in size while the proportion of connective tissue remained unchanged The increase in weight of the adult heart predominantly by hypertrophy has been observed by other workers both experimentally in dogs and in autopsy studies of humans In infants and in neonatal dogs by contrast increase in heart weight occurs by hyperplasia Experimental evidence relating the amount of myocardial collagen to the degree of ventricular enlargement has been equivocal In hypertrophy caused by valvular disease the content of myocardial collagen increases[3] whereas in thyroxine induced hypertrophy the total collagen decreases[3] Thus a mechanically induced ventricular hypertrophy may decrease ventricular wall hypertrophy by increasing total collagen while a metabolically mediated collagen loss may allow the ventricles to dilate because of increased compliance The human hearts in the present series appear to be more closely akin to the mechanical interpretation

Similar quantitative studies of the myocardial constituents were performed on autopsied patients with chronic mitral incompetence and hypertensive heart disease[6] Myocardial fiber diameter and proportion of interstitial tissue were obtained from computer analysis of enhanced photographs These workers noted a somewhat higher proportion of interstitial tissue than we did (32% against our 25%) but this may be due to the avoidance in our method of large vascular spaces and artifactual tissue spaces They also found a more than proportionate increase in patients with severe mitral incompetence which may correspond to our qualitative observations of expansive striae in chronically dilated hearts These workers found a diffuse hypertrophy in both groups of diseased hearts similar to our observations

It could be argued that the increase in perivascular connective tissue seen in some enlarged hearts in this study is mostly ischemic in nature with the hypertrophied myocardium outrunning its blood supply That this is not the case is

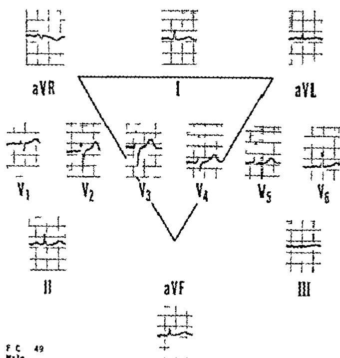

Fig 1 The ECG of a 49 year old male patient with a six month history of angina pectoris The treadmill test was positive the myocardial scan showed absent septum perfusion and coronary angiography revealed occlusion (100%) of the LAD at its origin and 95% narrowing of the principal diagonal at its origin

grams electrocardiograms and clinical records of 274 patients studied at Loma Linda University Medical Center Loma Linda California over a four year interval were analyzed The series with obstructive coronary artery disease consisted of 178 patients with chest pain most of whom had greater than 70% estimated cross sectional obstruction in one or more coronary arteries The ECGs of 96 patients without angiographic evidence of obstructive coronary artery disease were reviewed for ECG changes of the syndrome

A 12 lead electrocardiogram recorded on a high sensitivity paper was examined by two observers for absence of Q waves in Leads 1 aV_L V_5 and V and evidence of myocardial ischemia and/or infarction Records showing absence of Q waves with clockwise rotation on the long axis right or left bundle branch block and bilateral bundle branch block were excluded Some patients were exercise stressed on a computer controlled treadmill with three minute work loads beginning with 1 7 MPH at a 5% grade increasing to 1 7 MPH at a 10% grade 2.5 MPH a 12% grade 3 4 MPH at a 14% grade and MPH at a 16% grade The exercise was contin up to the point of fatigue chest pain or dysp Heart rate arterial pressure ECG morphol and symptoms were continuously monito throughout Exercise stress testing was not d on patients with recent acute myocardial pa

Selective coronary arteriography was car out by the Judkins technique[3] Ventriculogra was performed and recorded in the RAO degree and LAO 20 degree projections u biplane cineradiography The coronary arte were imaged in the AP RAO 20 degree LAO degree lateral and LAO craniocaudad pro tions using 35 mm cineradiography and 100 m photofluorography

The extent of artery narrowing was estima from the multiprojection views of the coron arteries The narrowing was expressed as a p cent cross sectional obstruction and the agr ment among different arteriographers of t extent of narrowing was remarkably close.

In analyzing the topography of obstruct coronary artery disease the major coron arteries were divided into proximal mid a distal regions For the left anterior desce d the region from the origin to the take-off of t first septal perforator was designated proxim the region extending from the first septal perf tor to the take off of the second anterior l ventricular branch (second diagonal) was cal the mid and the remaining artery was called t distal region The proximal region of the circu flex artery extended from its origin to the take of the obtuse marginal artery the mid reg extended from the obtuse marginal to the pos olateral left ventricular artery or posterior d scending artery and the distal segment extend to the remaining posterior continuation(s) of t circumflex The proximal region of the ri coronary extends from the take off to the ac marginal artery the mid region extends from t acute margin to the posterior descending and t posterior descending extends as the distal co uation of the artery

In some patients following coronary arter raphy 99m technetium microspheres 2.6 to 3 µCi were injected into the left coronary arte and 131 1 macroaggregated albumin 131 to 1 µCi were injected into the right coronary arter Other patients received differing amounts of 99

Coronary arteriograms and myocardial scintigrams in the electrocardiographic syndrome of septal fibrosis†

Renzo Romanelli M D *
William H Willis Jr M D **
Winston A Mitchell M D ***
Robert J Boucek M D ****
Miami Fla and Loma Linda Calif

In 1956 Burch[1] described the absence of Q waves in Leads 1 V_5 and V_6 in electrocardiograms (ECG) without left bundle branch block or clockwise rotation of the heart and introduced the ECG syndrome of septal fibrosis This description was followed by a necropsy study of 1 184 hearts 127 of which had histologic evidence of septal fibrosis[2] One hundred and one of the 127 hearts had the ECG syndrome of septal fibrosis only 2% had the ECG syndrome without morphologic evidence of septal fibrosis Subsequently other authors substituted the term left septal block for the ECG syndrome of septal fibrosis

Witham surveyed 200 patients with classical angina pectoris and identified 40 patients with nondiagnostic ECGs The vectorcardiograms (VCGs) of these 40 patients could be divided into seven patterns each of which identified myocardial infarction One of these patterns was the equivalent of Burch s ECG syndrome of septal fibrosis the Q loop of initial septal depolarization was absent and the abnormal initial vector in the horizontal and saggital planes extended beyond the expected time for completion of trans septal depolarization Witham considered this VCG abnormality as indicating septal infarction

As part of a continuing effort to refine the clinical assessment of coronary pathology we examined for relationships between obstructive coronary artery disease myocardial perfusion and the ECG syndrome of septal fibrosis in a series of patients studied with coronary arteriography and myocardial scintigraphy It was learned that patients with angina pectoris and the ECG syndrome of septal fibrosis have a higher incidence and a more extensive narrowing of the proximal LAD by obstructive coronary artery disease and a greater ventricular septal hypoperfusion than patients without the syndrome The fact that the ECG syndrome of septal fibrosis occurs in only 4% of age matched patients with angiographically determined coronary arteries free of obstructive disease strongly supports the usefulness of this ECG finding in identifying a subset of angina pectoris patients with a high probability of proximal LAD disease and left ventricular hypoperfusion

patients in the three groups patients with the ECG syndrome of septal fibrosis (Groups A and B) had a mean narrowing of 74% in contrast to 54% for patients without the syndrome (Group C)

One hundred and forty six patients had myocardial scintigraphy 62 with and 84 without the ECG syndrome of septal fibrosis (Table IV) Nearly 60% of the patients with the ECG syndrome of septal fibrosis (Groups A and B) have abnormal perfusion of the ventricular septum as opposed to 23% of the patients without septal fibrosis (Group C) a highly significant difference ($p < 0\ 001$) The percentage of patients with abnormal perfusion of the remaining left ventricle may also be greater in patients with (Groups A and B) than in patients without the ECG syndrome of septal fibrosis (Group C) ($p < 0\ 05$)

As judged from the findings presented in Tables III and IV no differences in the proximal LAD pathology or in the extent of left ventricular hypoperfusion are seen in comparisons of Groups A and B patients

To determine the incidence of the ECG syndrome of septal fibrosis in individuals without angiographic evidence of obstructive coronary artery disease the ECGs of 96 randomly selected records from the Radiology Museum at Loma Linda were reviewed The patients presented with atypical angina like chest pain Out of these 96 patients only four had the ECG changes of septal fibrosis

Discussion

Sodi Pallares and colleagues in a definitive study on the depolarization activation of the ventricular septum in dogs reported the orientation of the initial QRS vector as proceeding from the left side (midway between the anterior and posterior edges of the septum at the juncture of the lower two thirds with the upper one third of the septal surface) towards the trabecular [illegible] and the apex of the right ventricle The L[illegible] muscle mass activated on the left side of [illegible] septum generates a voltage field that inscribe[illegible] Q wave in leads I aVL V4 V5 and V6 A [illegible] initial septal depolarization from left to r[illegible] occurs for the human heart and an absence [illegible] Q wave in Leads I aVL V4 V5 and V6 reflec[illegible] according to Goldman[3] a parallel orientation [illegible] the ventricular septum with respect to the ex[illegible] ing electrodes scarring of the middle third of [illegible] ventricular septum left bundle branch block [illegible] preexcitation syndromes where the initial f[illegible] proceed anteriorly from right to left

A positive correlation between the severity [illegible] obstructive lesions in the proximal LAD and [illegible] ECG syndrome of septal fibrosis (Table I[illegible] reflects the key role of the LAD in transpor[illegible] blood to the ventricular septum The reg[illegible] where the left bundle branch ramifies and [illegible] initial ventricular septal depolarization vec[illegible] commences is supplied by proximally loca[illegible] septal penetrating branches from the LA[illegible] Atheromatous lesions proximal to the first se[illegible] perforating branch causing a significant (< [illegible] luminal narrowing would therefore reduce [illegible] blood flow to the ventricular septum and ca[illegible] ischemic injury loss of myocardium and ul[illegible] mately fibrosis in the region of the penetrati[illegible] His Purkinje bundle responsible for the in[illegible] septal depolarization Group C patients on [illegible] other hand with a lower incidence and extent [illegible] critical proximal LAD narrowing would hav[illegible] reduced incidence of septal fibrosis

Finding approximately 60% of patients with [illegible] ECG syndrome of septal fibrosis having abnorm[illegible] ventricular septal myocardial scintigrams (Ta[illegible] IV) represents a positive correlation between [illegible] near 75% narrowing of proximally loca[illegible] obstructive LAD lesion (Table III) and reduc[illegible] blood flow to the ventricular septum This 6[illegible] value contrasts sharply with the 23% value f[illegible] Group C patients without the ECG syndrome [illegible] septal fibrosis and where the extent of atheroma[illegible] tous narrowing of the proximal LAD is only [illegible] (Table III)

A more extensive coronary pathology and [illegible] ventricular hypoperfusion might have been pr[illegible] dicted for Group B as compared to Group [illegible] patients with the ECG syndrome of septal fibro[illegible] sis The fact that the two groups are ind[illegible] guishable by the various examinations includ[illegible] this study points up the serious implicatio[illegible]

Table I Patients with and without the ECG syndrome of septal fibrosis

technetium microspheres injected down the two coronary arteries At the end of the injections the patient was taken to the Nuclear Medicine Section and multiple views with an Anger camera were integrated in a data acquisition storage processing and display system using a computer controlled color coded display system developed by Adams and associates[8] The images were photographed separately as a series of 10 color coded isocount contours in spectral sequence The channel with the maximum counts was arbitrarily assigned the color red and each 10% change in counts resulted in a different color The scintigrams of the left and right coronary circulations appeared separately in combination and color Heparin (2 500 to 5 000 units) was given intra arterially at the beginning of the study and was reversed by protamine intravenously at the end of the procedure

Results

The patients were divided into four groups Groups A B and C were patients with angina pectoris—Group A patients with the ECG syndrome of septal fibrosis (Fig 1) Group B patients with the ECG syndrome of septal fibrosis and ECG changes of myocardial ischemia and/or infarction Group C patients with ECG changes of myocardial ischemia and/or infarction but *without* septal fibrosis Group D was composed of patients with chest pain but normal coronary arteries as shown by coronary arteriography Thirty patients were in Group A 35 in Group B 113 in Group C and 96 in Group D (Table I)

The age and sex distribution for Groups A B and C patients with angina pectoris is similar but a high percentage of females occurs in Group D patients The duration of angina pectoris is similar in patient Groups A B and C Of the 38

Dobutamine is a new synthetic catecholamine systematically formulated by Tuttle and Mills[1] Animal experiments demonstrated that this compound significantly increased ventricular contractility and cardiac output in a dose range which had little to no effect on heart rate and systemic blood pressure[2,3] Short and long term infusions of dobutamine in patients with cardiac failure also improved ventricular performance and increased cardiac output while decreasing left ventricular filling pressure and systemic vascular resistance these beneficial effects were achieved without a significant increase in afterload or heart rate [4] This laboratory previously reported that the mean cardiac index and left ventricular function parameters (echocardiograms and systolic time intervals) remained improved above baseline values 30 minutes after the discontinuation of a 72 hour dobutamine infusion (in patients with congestive cardiomyopathy and severe cardiac failure) symptomatic improvement [illegible]sisted up to one week post infusion in 68% of t[illegible] patients The purpose of this study is to de[illegible]mine whether prolonged infusion of dobuta[illegible] results in persistent symptomatic and or ob[illegible]tive improvement of cardiovascular functio[illegible] patients with low output cardiac failure

Methods

Patient population The 38 patients selected [illegible] the study had symptoms of severe left h[illegible] failure There were 29 men and nine women [illegible] age range was 17 to 73 years the mean a[illegible] 51 2 years The diagnosis of congestive ca[illegible]myopathy (COCM) was made by history p[illegible]cal examination and cardiac catheteriza[illegible] Patients who had a greater than 50% occlus[illegible] a coronary artery by angiography were excl[illegible] from the study Also excluded were patients [illegible] had consumed more than one drink of alcohol [illegible] day for the three months prior to study [illegible] etiology of the heart disease was commonly i[illegible]pathic (20 of 38 53%) but other factors were [illegible] important (Table I) Frequently two fac[illegible] such as alcohol and hypertension may h[illegible] contributed The protocol was approved by [illegible] Human Research Committee

This group of 38 patients can be further ch[illegible]acterized by their symptoms physical fi[illegible] electrocardiograms and hemodynamic data T[illegible] symptoms at time of study included dysp[illegible] [illegible] of 38 100%) peripheral edema (20 of 38 5[illegible] atypical chest pain (18 of 38 47%) easy fatig[illegible]bility (10 of 38 26%) palpitations (nine of [illegible] 24%) and abdominal swelling (nine of 3[illegible] [illegible] The most prominent physical findings [illegible]

what might be considered a minor ECG abnormality the loss of Q wave from the initial depolarization through the ventricular septum

It may be more than coincidence that the 23% of patients without the ECG syndromes of septal fibrosis had abnormal septal scintigrams while Burch and De Pasquale[2] found a 20% incidence of histologically proven septal fibrosis in the 1 184 hearts with previous ECG evidence of normal septal depolarization A most likely explanation for this similarity is that septal fibrosis or infarctions in regions remote from the initial depolarization pathway do not affect the Q wave inscription in the ECG leads subtending the ventricular septum

The 96% positive exercise stress response the significantly higher incidence of proximally located obstructive lesions of the LAD (Table III) and the higher percentage of abnormal ventricular septal and left ventricular myocardial scintigrams (Table IV) coupled with the infrequency of the ECG syndrome of septal fibrosis in patients with nonobstructive coronary artery disease (4%) when viewed together provide compelling evidence that the ECG syndrome of septal fibrosis is a useful clue for identifying a subset of angina pectoris patients with advanced coronary artery disease of the proximal LAD and diffuse left ventricular hypoperfusion

Summary

Coronary artery disease (CAD) and myocardial perfusion were assessed by arteriograms and scintigrams (Technetium 99 microspheres alone or combined with Iodine 131 albumin macroaggregates) in 178 angina pectoris patients with and without the electrocardiographic (ECG) syndrome of septal fibrosis and with ≥70% obstruction in one or more coronary arteries The ECGs of 96 patients without angiographic evidence of obstructive CAD were also examined for the ECG syndrome of septal fibrosis Patients with the ECG syndrome of septal fibrosis have significantly higher incidences of positive exercise stress test of ≥70% narrowing of the proximal left anterior descending (LAD) artery of severe proximal LAD disease and of more extensive left ventricular hypoperfusion than patients without the ECG syndrome The fact that only 4% of patients without obstructive CAD have the ECG syndrome of septal fibrosis indicates the usefulness of the syndrome in identifying a subset of angina pectoris patients with advanced CAD of the proximal LAD and diffuse left ventricular hypoperfusion

The assistance of Mrs Heidi Fowler and Mrs Nan Blanchard in preparing the manuscript is gratefully recognized

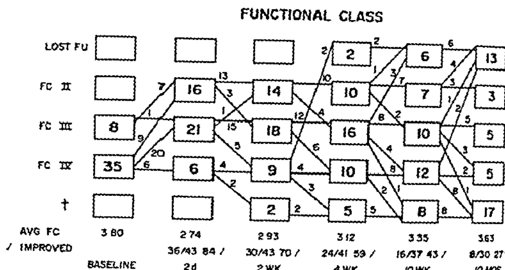

Fig 1 This graph details the number of patients in each functional class *(FC)* at each time period from baseline to 10 months after completion of the dobutamine infusion If we could not contact a patient he was considered lost to follow up *(Lost FU)* Those who died (†) were considered to be in *FC IV* for average FC determinations those lost to follow up were not included in average functional class determinations. Only those patients in a higher functional class compared to their baseline were considered improved for the percent improved of this graph.

functional class determination via telephone interviews

Results

The 38 patients received a total of 43 three day infusions of dobutamine five patients received the drug twice Every patient improved his cardiac function during the infusion as measured by the %ΔD and the PEP/LVET The average increase of %ΔD was 6 8% ± 0 7 ($\bar{x}$ ± SEM $p < 0\,001$) and the average decrease of the PEP/LVET was 0 16 ± 03 ($\bar{x}$ ± SEM $p < 0\,001$) Most patients continued to have subjective and objective evidence of improved left ventricular function after discontinuation of the drug

The improvement of functional class (FC) after dobutamine is shown in Fig 1 The average FC of all patients prior to dobutamine was 3 8 Two days after completion of dobutamine the average FC was 2 7 and at two weeks it was 2 9 Even at four and ten weeks the FC was 3 1 and 3 4 By 10 months however the average FC was 3 6 The number of patients improved decreased from 83% at two days and 70% at two weeks to just 27% at 10 months

Results of serial systolic time intervals are shown in Fig 2 The data were best organized over four time periods If a patient had more than one measurement during this interval the data were averaged Those patients studied maintained a significant ($p < 0\,001$) decrease of the PEP/LVET over pre drug control at all fou periods Similarly the echocardiographic % shown in Fig 3 This shows a signi ($p < 0\,05$) improvement at 2 3 days and impressive changes at 4 3 weeks and 9 9 and at 10 4 months ($p < 0\,01$)

Fig 4 details the results of the systolic intervals after discontinuation of dobutami the time when measurements were taken change from baseline is shown Improvemen considered significant if there was a one sta deviation (–0 04) change [9] This standard d tion was established by sequential studi patients with chronic myocardial disease T patients who died of congestive heart failure considered as having deteriorated in their tion tests However those who died of arr mias embolus or other causes were not enter this table Those test results that indica change of –0 04 are connected by a solid line indicate improvement A lesser change or a r the PEP/LVET is shown by a broken line At time period seven days after dobutamine 67% of 30) had an improved PEP/LVET At t months 52% (12 of 23) were better and even months 31% (five of 16) had evidence of impr left ventricular function

The change of %ΔD from baseline is show Fig 5 Improvement was considered significa there was a 2% rise in this measurement The rise was considered significant because in a F

gallop rhythm in all 38 patients 92% (35 of 38) had a left ventricular protodiastolic gallop and 74% (28 of 38) had a left ventricular presystolic gallop. Right ventricular protodiastolic (13 of 38, 34%) and presystolic (11 of 38, 32%) gallop sounds were also noted. The murmur of mitral regurgitation was present in 61% (23 of 38) and tricuspid regurgitation was observed in 16% (six of 38) of the patients. The electrocardiograms often showed conduction disease. There were 11 patients (11 of 38, 29%) with complete left bundle branch block and 16 (16 of 38, 42%) with left intraventricular conduction delay. Also 11 patients (11 of 38, 29%) had a left axis deviation and three (three of 38, 8%) had a right bundle branch block. Arrhythmias were frequently recorded. Seven patients (seven of 38, 18%) had atrial fibrillation and twelve (12 of 38, 32%) had frequent premature atrial or ventricular contractions. Findings at catheterization were consistent with severe left heart failure. The angiographic ejection fraction ranged from 0.09 to 0.42 with a mean of 0.25 ± .02 ($\bar{x}$ ± SEM) and the cardiac index ranged from 1.5 to 2.9 liters/min/M² ($\bar{x}$ = 2.0 ± 0.1). The pulmonary wedge pressure averaged 23.4 mm Hg ($\bar{x}$ = 23.4 ± 1.9).

Infusion period and studies. Written informed consent was obtained from each patient. Dobutamine was delivered intravenously with a calibrated Harvard pump for 72 hours. Dobutamine was started at 2.5 mcg/kg/minute and was increased every 30 minutes in 2.5 mcg/kg/minute dose increments up to a maximal dose of 15 mcg/kg/minute. The maintenance dose for each patient was determined on the basis of data derived from the dose response phase and had to meet the following criteria: heart rate increase of < 120% of control, systolic blood pressure < 120% of control, pulmonary capillary wedge pressure < 140% of control, and premature ventricular contraction of < 12/minute. After six hours of the maintenance dose and daily thereafter, the dose was re-evaluated for each patient and was increased or decreased based on the criteria noted above.

The electrocardiogram was monitored continuously over the 24 hours prior to the infusion period and continually during the infusion. An echocardiogram and systolic time interval determinations were performed 30 minutes before the infusion began, daily during the infusion period and at intervals as discussed below. Systolic time intervals were obtained with an Electronics for Medicine VR6 or with a Smith Kline French Echoline 20 unit utilizing the specifications previously outlined.[9] The PEP/LVET was used as the measure of left ventricular performance. Echocardiograms were performed with a Unirad series C echoscope and an Electronics for Medicine VR6 recorder or an Irex echoscope with the SKF Echoline 20 recorder. The %ΔD was used as the echocardiographic determinant of left ventricular function and was derived from the formula:

Table I. Contributing factors to heart failure (38 patients)

Idiopathic	20 patients	53%
Alcohol	17 patients	45%
Hypertension	10 patients	26%
Possible viral disease	4 patients	11%
Peripartum	3 patients	8%
Diabetes	2 patients	5%
Amyloidosis	2 patients	5%

$$\%\Delta D = \frac{\textit{end diastolic diameter} - \text{end systolic diameter}}{\text{end diastolic diameter}} \times 100$$

The left ventricular free wall thickness and end diastolic diameter were measured at end-diastole prior to dobutamine infusion.

Follow-up information. Patients were contacted and were encouraged to return to the medical center for an interview, physical examination, and non-invasive measurement of left ventricular function. The functional class determinations were made by two of the investigators (D.V.U. and C.V.L.). Patients were considered lost to follow-up for functional class determination if we were unable to contact them or if they were started on additional drug therapy. Initiation of additional drug therapy was not necessarily a sign of dobutamine failure because many patients were placed in other studies after several months. Patients who died were considered to be in the unimproved functional category despite the fact that several patients had objective and subjective signs of improvement but died of an embolus or a dysrhythmia. Digitalis and diuretics were maintained at the same dosage level throughout the study. Vasodilators were not prescribed. Patients who were unable to travel were excluded from the non-invasive measurement portion of this study but were included in the

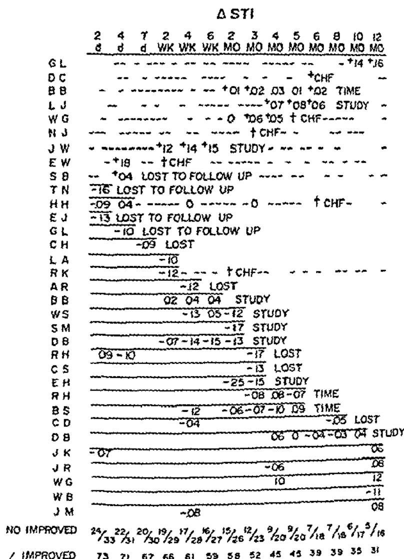

Fig 4 The change of each patient s PEP/LVET from baseline are shown Those who died (†) and the cause of death (*CHF* = congestive heart failure) are noted The study was completed while some patients were under observation (*Time*) some patients were placed on another study (*Study*) and some could not travel to the medical center for examination (*Lost* = lost to follow up) Those who had an improvement of less than –0 04 or who had a worsening of the ratio or who died are noted by a *dashed line* linking their initials to their data Those patients who had an improvement of greater than –0 04 of the PEP/LVET have a *solid line* linking their initials and running above their data Those who died or did not improve were considered to be unimproved for all 12 months of the study Those who improved the PEP/LVET were considered to be improved only for the time of observation The percent improved at each time period after dobutamine is shown at the bottom of the graph

diograms 22 (58%) had a decrease of their left ventricular diameter

The average survival of these patients from the onset of symptoms was approximately nine years and is illustrated in Fig 6 No patient has survived more than 20 years from the onset of symptoms The cause of death in the 17 patients who died during the time of the study was pulmonary embolus (six of 17 35%) intractable left heart failure (six of 17 35%) ventricular arrhythmias (four of 17 23%) and sepsis (… 17 6%)

Discussion

Therapy of congestive cardiomyopathy ha… ditionally been digitalis and diuretics Ther… a wave of popularity for extended bed rest i… 1960 s and the early 1970 s … This treat… decreased heart size in those with alcoh… peripartal … or idiopathic cardiomyop…

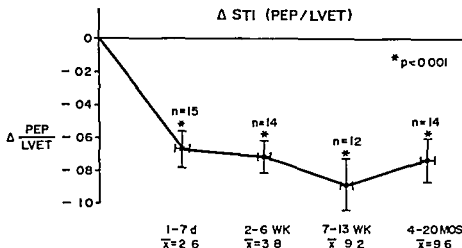

Fig 2 The change of the PEP/LVET of the systolic time intervals from baseline is shown at four time periods after dobutamine infusion The number of patients measured at each period is shown Some patients had two or more measurements made during a time period and these were averaged. *Brackets* represent the standard error of the mean

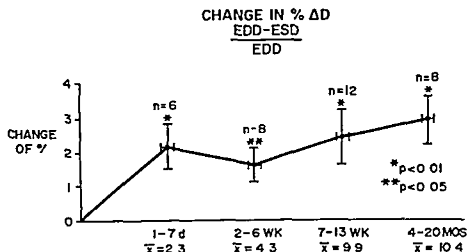

Fig 3 The change of the echocardiographic %ΔD from baseline at four time periods after dobutamine infusion is shown The number of patients measured during each period is shown Some patients had two or more measurements during a time period these values were averaged *The brackets* represent the standard error of the mean

of 15 patients with stable heart failure the one standard deviation of serial %ΔD measurements of the echocardiograms was 1 7% At one week after discontinuation of dobutamine 60% (18 of 30) had an improved %ΔD At two and six weeks 55% (16 of 29) and 50% (14 of 28) were still improved At three six and 12 months 48% (13 of 27) 42% (10 of 24) and 22% (four of 18) had a %ΔD at least 2% better than control

The left ventricular wall thickness (LVWT) had some prognostic implications Those patients who had symptomatic improvement had a thicker left ventricular free wall (corrected for body surface area) 0 59 cm/M² ± 03 (x̄ ± SEM) compared to those who did not improve 0 53 cm/M ± 04 Also only 24% (seven of 29) of those who improved had LVWT less than 0 5 cm/M while 56% (five of nine) of those who did not improve had LVWT less than 0.5 cm/M²

The left ventricular end diastolic diameter decreased slightly from an average pre dobutamine value of 6 58 ± 17 cm (x̄ ± SEM) to a post dobutamine diameter of 6 45 ± 14 ($p < 0.05$) Of the 38 patients who had echocar

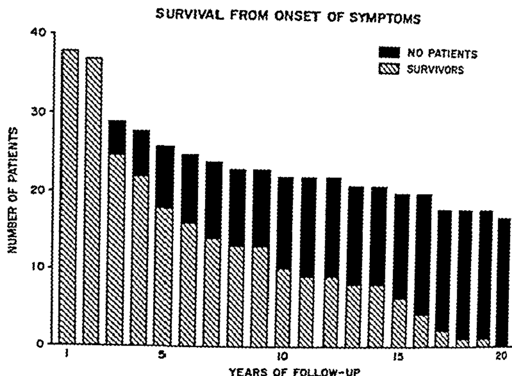

Fig 6 This graph demonstrates the survival of our 38 patients from the onset of symptoms The total number of patients is shown by the *height* of the bars Those who are still living at each year are illustrated by the *cross hatched portion* of the bars while those who have died are shown by the *solid portions* of the bars

ogy of the particular patient s heart failure before institution of veno or arteriolar dilators [2,29] Caution has been urged in the use of nitrates hydralazine and prazosin because of both pharmacologic effects and adverse reactions [29] Because of the potential adverse effects of vasodilators and because not all patients improve with vasodilators consideration should be given to inotropic agents in the treatment of congestive cardiomyopathy

This study demonstrated that dobutamine induced an improvement of myocardial function both during the three day infusion and in the follow up period Most of the patients (84%) had symptomatic improvement two days after infusion 59% continued to feel better at four weeks and 43% continued to feel better at ten weeks (Fig 1) This improvement was documented by non invasive testing The PEP/LEVT was significantly improved at three days four and 10 weeks and at 10 months (Fig 2) The echocardiographic %ΔD was similarly significantly improved (Fig 3) in those patients whom we could recall for testing The number of patients improved at each time period is similar for the two tests with approximately 50% still maintaining improvement at three months Even at six months, [illegible] and 42% were improved by PEP/LVET and the %ΔD

There was a small (1 4 mm ± 0 7 (p < 0.0[illegible]) but significant decrease of end diastolic diameter by echocardiogram after the three day infusion The patients who had a functional class improvement usually had a thicker left ventricular free wall (greater than 0 5 cm /M [2]) than those who did not respond This is consistent with Hamby's study [3] He found that the patients with thicker left ventricular walls had a better prognosis than those with a thin wall

The mechanism of the prolonged improvement of COCM patients after a three day infusion of dobutamine is not understood The downward spiral of a decreasing cardiac output increasing peripheral vasoconstriction and fluid retention may be corrected during the infusion period The reversal of this spiral may enable the ventricle to assume a new level of function with a reduced peripheral resistance Another possible mechanism for prolonged functional improvement may be related to increased coronary artery flow Dobutamine not only increases cardiac output but also by [illegible] of its beta −1 action dilates coronary arteries

Fig. 5. The change of each patient's echocardiographic % ΔD from baseline is illustrated. Those who died (†) and the cause of death (*CHF* = congestive heart failure) are noted. The study was completed while some patients were under observation *(Time)*, some patients were placed on another study *(Study)*, and some could not come to the medical center for further examination *(lost to FU)*. The patient's initials are connected to their data by a *dashed line* if the improvement was less than 2% or if the patient died (CHF). The initials are linked by a *solid line* that runs over the data if there was a 2% or greater improvement of the % ΔD. The percent improved at each time period is shown at the bottom of the graph.

and improvement was maintained for months in some of these patients.' This treatment has not had a great deal of popularity in recent years, however, because of the practical problems of maintaining strict bed rest. Also some investigators have found that in certain types of heart disease such as peripartal cardiomyopathy, heart size may return to normal without extended bed rest.' A compromise of a subdued life style is usually prescribed.

Acute alcohol intake alters myocardial mitochondrial and sarcoplasmic reticulum morphology, and chronic alcohol abuse leads to permanent destruction of myofibers with interstitial scarring. Thus the treatment of cardiomyopathic patients must include the avoidance of all alcohol. Discontinuation of alcohol after chronic abuse is associated with a gradual improvement of myocardial function over an eight week period. Before crediting any therapy with improvement of the status of patients with alcoholic cardiomyopathy, one must be sure that no alcohol has been consumed for at least two months.

Vasodilator therapy for heart failure is presently enjoying popularity. Several investigators have recommended consideration of the physiol

The increased coronary blood flow may enable some borderline ischemic regions of the subendocardium to repair hypoxic damage The salvage of such areas may improve ventricular performance These possibilities are currently being investigated

The weakness of our study is the absence of patient controls Because of the heterogeneity of COCM a controlled study would have to be very large to match etiologies age ventricular function and pressures Nevertheless a study should be performed in which patients would be randomized to control (digitalis and diuretics would be used in all groups) vasodilator therapy inotropic therapy and combined vasodilators and inotropes Such a study could recognize which patients benefit from each type of therapy in symptoms function and longevity

The therapy of congestive heart failure is expanding and dobutamine would appear to have a significant role Whether the therapy should be a single three day infusion intermittent or even continous infusions is undecided Finally an oral inotrope with properties similar to dobutamine would be of great value in the drug regimen of COCM

Summary

Dobutamine was given intravenously for three days to 38 patients with congestive cardiomyopathy The patients were followed by serial determinations of functional class and by non invasive measurements of left ventricular function systolic time intervals (PEP/LVET) and echocardiogram (%ΔD) The average functional class (FC) of this group was 3 8 prior to dobutamine but two days after completion the average FC was 2 7 by four weeks the average FC was 3 1 and by 10 weeks it was 3 4

The average PEP/LVET declined significantly ($p < 0\,001$) at three days four and nine weeks and at 10 months after the discontinuation of dobutamine infusion Also 67% (20 of 30) of patients had improvement of the PEP/LVET by greater than −0 04 at seven days Even two and six months after dobutamine 58% (15 of 26) and 39% (seven of 18) were improved Similarly the %ΔD was improved by at least 2% in 60% (18 of 30) at seven days and 55% (16 of 29) at four weeks At two and six months 50% (14 of 28) and 42% (10 of 24) were improved Those patients who did not improve their FC were more likely (five of nine) to have left ventricular free wall thickness (by echocardiogram) less than 0.5 cm /M Those who responded usually (22 of 29) had a ventricular wall thickness greater than 0.5 cm /M Although the mechanism of the prolonged improvement after a three day infusion of dobutamine is not understood this study suggests that dobutamine has a role in the therapy of chronic congestive heart failure

We would like to thank Patricia Huss R N, and Jackie Miller R N for the performance and measurement of the systolic time intervals and echocardiograms We would also like to thank Tami Griffith for the preparation of the manuscript

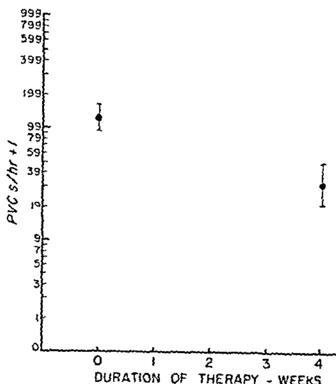

Fig 1 An illustration of the results of short term (4 weeks) acebutolol therapy on the incidence of PVCs Standard error of the mean is used in all instances

weeks of therapy all patients had a second chest x ray and repeat opthalmological testing All 20 patients had serum levels of acebutolol and its active acetyl metabolite measured approximately two to four hours after the last dose of the drug according to the method of Meffin and associates[4] The serum drug level estimations coincided with the day of the four week Holter recording

At the time of entry into the study 14 of 20 patients had a prior history of myocardial infarction with stable angina pectoris Two patients with a prior history of myocardial infarction had no post infarction angina All patients with prior myocardial infarction were at least three months post myocardial infarction at the time of the study entry Four patients with no history of prior myocardial infarction had stable angina None of the patients had unstable angina at the time of study entry Five patients had had saphenous vein bypass surgery performed at least one year prior to study entry for angina pectoris resistant to conservative medical management All 20 patients were in New York Heart Association Functional Class I or II without clinical evidence of congestive heart failure However four of 20 patients had on baseline chest x ray a cardiothoracic ratio of greater than 50% All 20 patients had normal renal and hepatic functi[illegible] No patient had a positive ANA titer prior t[illegible] study entry

On baseline electrocardiogram remote transmural myocardial infarction was present in e[illegible] of the 20 patients In the remaining 1[illegible] patients the electrocardiogram was either normal or revealed only nonspecific ST T changes One patient had complete right bundle branch block No A V block or resting heart rates of less than [illegible] beats per minute were observed in any of the patients

At the time of entry into the study seven of [illegible] patients had no symptoms suggestive of card[illegible] arrhythmia and were selected for the study on the basis of frequent premature ventricular contractions noted on 12 lead electrocardiograms d[illegible] during routine clinic visits One patient had s[illegible] copal spells unrelated to postural change me[illegible] bolic abnormality or neurological disease Twelve patients had unexplained d[illegible] spells with or without palpitations

The 24 hour Holter tapes were analyzed us[illegible] the Model 660 A Avionics electrocardiosc[illegible] and the following features were quantitated (1) the number of PVCs expressed as the number per hour (2) the number of episodes of paired PVCs and (3) the number of episodes of PVCs in r[illegible] of three or more For the purposes of this study three or more consecutive PVCs at a rate in excess of 120 beats per minute were considered to represent ventricular tachycardia Similar runs [illegible] rates between 60 and 120 beats per minute were considered to represent accelerated idioventricular rhythm The Model 660 A Avionics electroca[illegible] dioscanner allowed playback of the tapes [illegible] speeds of 1 30 60 and 120 times real time. T[illegible] detect and quantitate ventricular arrhythmias [illegible] used oscilloscopic display of one or two simul[illegible] neous channels of electrocardiographic leads [illegible] the R R interval and an R wave triggered [illegible] system and the Avionics arrhythmia analyzer The arrhythmia analyzer employed variabl[illegible] characteristics of prematurity QRS width, and amplitude to detect and quantitate ventricular ect[illegible] ectopy The frequency of ventricular [illegible] beats expressed as the number per hour [illegible] displayed on the scanner and a trend pr[illegible] record showed the hourly count of ventric[illegible] ectopic beats In addition all tapes were man[illegible] ly scanned and all areas of questionable accura[illegible] were verified by direct writeout and hand re[illegible] ing with evaluation of these rhythm strips [illegible]

The long-term suppression of ventricular arrhythmia by oral acebutolol in patients with coronary artery disease*

Beta blocking agents have enjoyed increasing popularity in managing post myocardial infarction patients since long term prophylactic administration of beta blocking agents to survivors of myocardial infarction has been shown to result in a decreased incidence of sudden death Many beta blocking agents with claims for less effects than propranolol on noncardiac beta receptors are currently undergoing clinical evaluation Acebutolol [(±) 1 (2 acetyle 4 butyramido phenoxy) 3 isopropylamino propan 2 ol hydrochloride] a relatively cardioselective adrenergic receptor blocking drug with weak sympathomimetic activity is one such drug Even though its efficacy when used both parenterally and orally in treating ventricular ectopy over a short period has been shown in several studies the long term efficacy and safety of oral acebutolol has not been well documented

Material and Methods

Patients for this study were selected on the basis of the presence of a minimum of 10 PVCs per hour (mean) present on a single 24 hour Holter monitor performed after discontinuing digitalis and antiarrhythmic drugs for at least one week During the entire study period patients continued to remain without concurrent therapy with digitalis preparation or other antiarrhythmic drugs Only patients with documented coronary artery disease were eligible for selection for the study Patients with congestive heart failure symptomatic chronic obstructive lung disease insulin dependent diabetes and significant opthalmological disease were also excluded Due to untoward effects noted with other beta blocking agents on the eye all patients being considered for the study had detailed opthalmological testing by an opthalmologist and any patient with a significant opthalmological problem was excluded

After obtaining informed consent 20 male patients with an average age of 57 years and a minimum of 10 PVCs per hour (mean) on baseline Holter monitoring had complete physical examination chest x ray 12 lead electrocardiogram and laboratory tests including an antinuclear antibody (ANA) titer performed at baseline Oral acebutolol was then commenced at a dose of 100 mg orally every eight hours and was continued for fours weeks During this period weekly 24 hour Holter monitoring was performed using a two channel Avionics Model 445 electrocardiocorder The daily dose and the frequency of acebutolol were adjusted depending on the effect of the drug on the PVC frequency noted during weekly Holter monitoring At the end of four

therapy to a geometric mean number of 32 PVCs per hour ($P < 0.005$) However when the responses of the individual patients were considered PVC reduction from baseline values was greater than 90% in four patients and greater than 70% in 11 of 20 patients In the remaining nine patients PVC reduction from baseline values was less than 50% in fact in six of these nine poorly responding patients there was no reduction in PVCs from baseline values (Table I)

In six patients with paired PVCs at baseline paired PVCs were noted after four weeks of acebutolol therapy in four patients (Table I) Three of these four patients were non responders (patients showing less than 70% total PVC reduction) Even though the two patients with baseline PVT had no PVT following therapy two other patients without PVT at baseline had one three beat episode each of PVT after four weeks of acebutolol therapy Again one of these two latter patients was a non responder

In all 20 patients the mean serum level of acebutolol was 759 ± 353 (standard deviation) ng/ml The corresponding serum level of its acetyl metabolite was 1 756 ± 797 (SD) ng/ml giving a metabolite to unchanged acebutolol of 2 3 1 The mean serum levels of acebutolo… its metabolite in the 11 patients responding… greater than 70% PVC reduction 723 ± 29… ng/ml and 1 807 783 (SD) ng/ml respect… were not significantly different from the … sponding serum levels in the nine rema… non responders 796 ± 411 (SD) ng/ml… acebutolol and 1 705 ± 811 (SD) ng/ml f… acetyl metabolite

cardiologist During analysis of the data the term complex PVCs was used to mean an arrhythmia with two or more of the following features during the 24 hour Holter monitoring greater than 10 PVCs per hour paired PVCs and paroxysmal ventricular tachycardia (PVT)

These data were analyzed by use of Student s t test In comparing means across time the paired t test was used In comparing groups of responders versus non responders the unpaired t test was applied For the PVC data a variance stabilizing transformation was applied to the data before analysis by the t test This transformation amounted to adding the number one to each PVC count and then taking the natural logarithm (essentially this amounts to testing for significant differences among geometric rather than arithmetic means)

During the four weeks of therapy acebutolol was administered on a thrice daily schedule in 12 of the 20 patients and on a four times daily schedule in the remaining eight patients The average daily dose of acebutolol used in the 20 patients during the four week trial was 1 100 mg (range 600 to 1 600 mg)

In order to determine the long term efficacy and safety of the drug nine of the 11 patients responding with greater than 70% PVC reduction from baseline values during the four weeks of acebutolol therapy who consented to join the long term evaluation were continued on acebutolol for 12 months The two patients who did show a satisfactory response at the conclusion of the short term study who were excluded from the long term study were one patient who left the state of Arkansas and was not available for long term participation and a second who decided not to participate in a long term study for personal reasons During the 12 months of therapy all patients returned for 12 lead electrocardiograms and physical examinations every four weeks At the 1 month 4 month 8 month and 12 month visits all patients in addition had 24 hour Holter monitoring chest x ray laboratory tests including an ANA titer and detailed opthalmological testing During the long term evaluation the acebutolol dosage and frequency were adjusted depending on the clinical response and the frequency of ventricular ectopics as noted on the serial 24 hour Holter monitor recordings

The average daily dose of acebutolol used in the long term trial was 1 300 mg (range 600 to 1 600 mg per day) The acebutolol was administered on

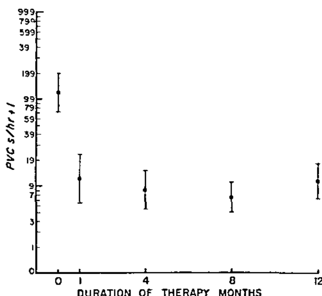

Fig 2 An illustration of the response of long term acebutolol therapy 0 = PVC incidence at baseline (pre drug) Standard error of the mean is used in all instances

a thrice daily basis in three of the nine patients and on a four times daily schedule in the remaining six patients The characteristics of the nine patients on the long term trial were as follows (1) average age 56 years (2) all had stable angina pectoris (3) six of nine patients had had prior myocardial infarction not less than three months prior to study entry and (4) four of nine patients had had prior saphenous vein bypass surgery at least one year prior to study entry

Of the nine long term subjects three were free of symptoms suggestive of cardiac arrhythmia at baseline Six patients has unexplained dizzy spells with or without palpitations prior to starting acebutolol therapy None of the long term study patients gave a prior history of syncope or cardiac arrest

The Holter recordings performed on the long term evaluation were analyzed in the same way that the short term Holter recordings were analyzed and the same arrhythmia characteristics were quantitated

Results

Short term trial (four weeks of therapy) The results of short term acebutolol administration in the 20 patients studied are shown in Fig 1 When the response to therapy of the whole study group was considered the geometric mean number of PVCs per hour in the 20 patients before therapy (125) was significantly lowered by acebutolol

Table II Complex PVCs during therapy in all nine patients

	>10 PVCs/hr	Paired PVCs	PVT
Baseline	9 pts	5 pts.	1 pt
12 month visit	5 pts	2 pts	0 pts.
At least once during therapy	8 pts	4 pts.	2 pts

PVC = premature ventricular contraction PVT = number of episodes of paroxysmal ventricular tachycardia.

nificant fluctuations in PVC counts once therapy was commenced

Prior to acebutolol therapy the geometric mean number of PVCs per hour in the nine study patients was 117 and at the 12 month visit the geometric mean number of PVCs per hour was 11 ($P < 0.001$) The geometric mean number of PVCs noted at the 1 month 4 month 8 month and 12 month Holter recordings was nine per hour and was not significantly different from the geometric mean number of PVCs at the 12 month visit (11 per hour)

After 12 months of acebutolol therapy the percentage reduction in PVCs noted at the 12 month visit was greater than 90% in four of nine patients greater than 80% in six patients and greater than 60% in seven patients One patient had a 46% reduction in PVCs and one patient had no reduction in PVCs at the 12 month visit This patient who did not respond to long term acebutolol therapy who also happened to have the smallest number of baseline PVCs (14 per hour) had excellent PVC control through eight months of therapy and showed a sudden unexplained increase in PVCs to 58 per hour at the 12 month visit (Table I)

Even though over all decrease in PVCs was impressive complex features of ventricular ectopy persisted despite acebutolol therapy in some patients This is shown in Table II in which it can be seen that greater than 10 PVCs per hour and paired PVCs persisted during therapy in some patients Paired PVCs present at baseline in five patients were abolished on the four Holter recordings during therapy in only two patients PVT was abolished in the one patient having PVT at baseline However in two other patients PVT was noted during therapy Each of these two patients had one three beat episode of PVT each on a single Holter recording done during therapy One of these patients also had one episode of accelerated idioventricular rhythm during therapy However all patients remained symptom[...] in spite of these observations

tients showing greater than 70% PVC reduction) was 80 beats per minute and 63 beats per minute respectively (P < 0 001) and in the nine non responders it was 73 and 63 beats per minute respectively (P < 0 001) However the difference in the bradycardic response following acebutolol therapy between the 11 responders and the nine non responders was not statistically significant

The mean systolic blood pressure before and after four weeks of acebutolol therapy was 131 and 126 mm Hg respectively (not significant) Similarly no significant differences were noted in the PR interval the QRS and the corrected QT interval following short term acebutolol therapy None of the patients had atrioventricular block during therapy One patient developed a single episode of accelerated idioventricular rhythm during sleep However a further increase in the dose of acebutolol in this patient subsequently did not result in a recurrence of this arrhythmia No symptomatic bradyarrhythmias were noted in any of the patients

Side effects during short term therapy (Table I)—Four patients experienced evidence of transient mild gastrointestinal intolerance which did not need dosage adjustment of acebutolol One patient developed a 1 cm increase in heart size on chest x ray with a decreased exercise tolerance after two weeks of acebutolol therapy However the addition of a diuretic agent quickly reversed both the symptoms and the cardiomegaly No hematological or ocular side effects were noted during short term therapy in any patient

Effects of short term acebutolol therapy on angina—All 17 of 20 patients thought to have stable angina by history prior to entering the study had significant subjective decrease in angina following acebutolol therapy However no objective measurements of angina relief by the drug in the form of exercise testing was carried out during the study

Long term trial

The response to long term acebutolol therapy over 12 months in the nine patients is depicted in Fig 2 This figure shows a highly statistically significant and consistent decrease in PVCs from baseline values which was then maintained throughout the 12 month period with only insig

dose of propranolol[14] In the present study the concentration of the acetyl metabolite after oral administration of acebutolol was consistently higher than the plasma concentration of the parent compound Similar results have been reported earlier by Winkle and colleagues[15]

With potential benefits in the management of hypertension[16] and angina,[17] as well as cardiac arrhythmia[3 4] beta blocking agents such as acebutolol enjoy a unique role in treating patients with organic heart disease where the triad of angina hypertension and cardiac arrhythmia often coexist even though the efficacy of acebutolol in each of these three conditions is yet to be well established The results of the present study, along with the other studies on the short term use of acebutolol as an antiarrhythmic agent suggest that this drug may become a useful addition to the clinician s currently inadequate antiarrhythmic armamentarium

Summary

The short term efficacy of oral acebutolol was evaluated in 20 patients with coronary artery disease and frequent premature ventricular contractions (PVCs) by serial 24 hour Holter monitoring before and while the patients were receiving an average daily dose of 1 100 mg of acebutolol for four weeks Fifty five percent of the 20 patients showed a greater than 70% PVC reduction from baseline values The only serious side effect during short term therapy was mild reversible cardiac decompensation in one patient The long term safety and continued efficacy of acebutolol was then evaluated over the next 11 months in nine of the 11 patients showing greater than 70% PVC reduction at four weeks Two thirds of these nine patients continued to show greater than 80 PVC reduction from baseline values at 12 months One patient developed alopecia during long term therapy The majority of patients not responding well to acebutolol at four weeks had an actual increase in PVCs on acebutolol therapy We conclude that acebutolol produces long term effective reduction in PVCs without serious toxicity in the majority of patients with ventricular ectopy However this drug appears to either produce an excellent response or no response with regard to PVC control in most instances

The authors wish to express their appreciation to Ives Laboratories Inc 685 3rd Ave New York for providing the acebutolol and placebo capsules used in this study We also wish to thank Roger L. Williams, M D Medical D[illegible] Drug Studies Unit University of California a S[illegible] for the drug level assays done at his laboratory Dr [illegible] Walls, Ph D., Professor and Head Biometry Division, [illegible]sity of Arkansas Medical Sciences Campus, for the [illegible] analysis of the data Ms. Jean Klemazew[illegible] for [illegible] assistance and Ms Barbara Carter for secretarial [illegible]

uggests a similar tendency with acebutolol since 5% of the 20 patients showed a greater than 70% VC reduction and 30% had no reduction in VCs from baseline values However a larger atient population will have to be studied before efinite conclusions can be drawn in this regard ince beta blocking agents have been shown to be ost *beneficial in patients displaying evidence* of icreased activity of the autonomic nervous sys em with resting tachycardia[1, 11] it is possible hat patients with ventricular ectopy and slower esting heart rates tend to have a less dramatic esponse to therapy with beta blocking agents ith regard to antiarrhythmic efficacy However n our group of 20 patients even though both of he 11 responders and the nine non respond rs did demonstrate a significant bradycardic esponse from baseline levels the difference in the lecrease in heart rate between the two groups was iot statistically significant Thus an excessive radycardic response or a lack of a bradycardic esponse cannot be said to explain why 55% of our 0 patients showed an excellent response and the emaining 45% showed a poor response or no esponse Since the serum levels of the drug and ts acetyl metabolite were not significantly differ nt in these two groups of patients drug toxicity r inadequate blood levels cannot be said to be he cause of this excellent or poor response with o tendency to obtain intermediate results with cebutolol therapy

Even though the total abolition of complex haracteristics of ventricular ectopy such as pair ng runs of PVC and greater than 10 PVCs per our was not observed with acebutolol therapy in he long term trial it must be considered that the atients in the study population had only sporad c episodes of runs of PVCs both at baseline and during drug therapy and a separate study using patients with more serious and more frequent pisodes of ventricular tachycardia will have to be tudied before a judgment on the efficacy of acebutolol in suppressing complex ventricular arrhythmia can be reached However the present study does suggest that in the small group of patients studied acebutolol is effective in signifi cantly reducing the incidence of isolated PVCs in the majority of patients

Before the safety of acebutolol with long term use can be fully evaluated a much longer experi ence using a much larger patient population than has been observed in the present study will have to be evaluated However in the present study the only patient who needed to have the drug discontinued due to side effects was the single patient who developed alopecia Alopecia has also been noted rarely as a side effect of propranolol therapy The remaining side effects noted were either transient or were reversed by simple coun teractive measures without decreasing the acebu *tolol dosage or stopping the drug Ocular side* effects noted with practolol[5] another beta block ing agent were notably absent with acebutolol in spite of closely monitoring patients for such side effects Likewise no hematological side effects were observed

The present study was not designed to evaluate the relative cardioselectivity of acebutolol Hence in our study the effects of the drug on pulmonary functions could not be commented on since pulmonary functions were not evaluated objectively with spirometry and blood gas deter minations and none of the patients had symp- tomatic chronic obstructive pulmonary disease However the absence of respiratory symptoma tology in our 20 patients during acebutolol thera py is noteworthy Decalmer and colleagues[3] have reported that most of the so called cardioselective beta blocking agents including acebutolol when given to patients with bronchial asthma do pro duce some impairment of ventilatory function But their effects are less depressant in patients with bronchial asthma than the non cardioselec tive beta blocking agents such as propranolol

Even though patients with prior or current cardiac decompensation were excluded from the present study one patient developed mild easily reversible symptoms suggestive of congestive heart failure during the four week trial of acebu tolol Thus as with other beta blocking agents patients with borderline states of cardiac compen *sation who require therapy with drugs such as* acebutolol will have to be observed carefully for evidence of cardiac decompensation

Measurement of serum levels of acebutolol the parent compound and its acetyl metabolite revealed no significant difference in the serum level of either agent between the patients re sponding adequately and the remaining non responders Adequate therapeutic levels for antiarrhythmic efficacy of acebutolol have yet to be worked out fully But the wide range of plasma levels of both agents measured regardless of the therapeutic response and dose is similar to the lack of correlation between plasma propranolol levels in different patients given the same oral

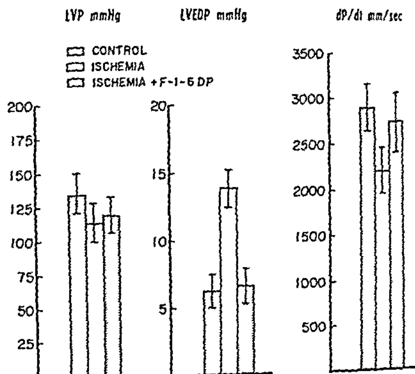

Fig 1 The effect of fructose-1 6-diphosphate (FDP) on left ventricular pressure *(LVP)* left ventricular end-diastolic pressure *(LVEDP)* and the rate of ventricular pressure rise *(dp/dt)* when administered intravenously at 45 minutes after onset of acute myocardial ischemia in 10 dogs The administration of FDP continued as a constant infusion at the rate of 1.25 mg /kg /minute until the termination of the experiment (see text) The standard errors of the mean are indicated.

the femoral vein was used for administration of FDP and other drugs and fluids Prior to induction of ischemia arterial pO_2 pCO_2 pH and CO_2 combining power were verified as to whether they were in physiologic range and if not appropriate adjustments of respiratory volumes and rates were made

Acute myocardial ischemia was induced by either ligating or obstructing a major branch of the left coronary artery with a balloon catheter

Open chest In 10 dogs the heart was suspended in the pericardial sac after thoracotomy and the left anterior descending artery (LAD) was dissected free A control period of 1 hour was allowed prior to ligation of the LAD During this period ventricular and aortic pressures cardiac output measurements and epicardial ECG tracings were recorded The epicardial ECG recordings were unsatisfactory (even though we used cotton wick electrodes suspended on a spring) because artifacts due to motion caused by the respirator made them unreliable Therefore after the ligation of the LAD the chest was closed and precordial ECG was monitored throughout the experiment In this group five animals received FDP and five controls received equimol[ar dex]trose intravenously

The myocardial district distal to an arterial obstruction rapidly becomes ischemic and only a limited period of time is available to restore sufficient energy production before the damage becomes irreversible It has long been hoped to fill such a void in anaerobic energy production in the ischemic myocardium by stimulation and acceleration of the Embden Meyerhof pathway This has been done experimentally and clinically administering quantities of glucose insulin and potassium Since Sodi Pollares and associates first reported success with such therapy for acute myocardial infarction many clinical and experimental contradictions have arisen and both the results and the hypotheses used to support early and present claims have in one way or another been challenged[3 8] The most important criterion raised and experimentally documented is that the Embden Meyerhof pathway catabolic activity is not increased but rather impaired by the progressive inactivation of several enzymes in the course of acute myocardial ischemia[1 3] A critical step in ischemic inhibition of glycolysis appears to be inactivation of phosphofructokinase induced by progressively increasing intracellular acidosis[6 1 5] thus depriving the pathway of fructose 1 6-diphosphate (FDP) One approach to relieve this would be to provide FDP exogenously Such an increase in the cytoplasmic concentration of FDP should stimulate glycolysis by intervening as a metabolic regulator and substrate to permit function at higher rates This study was designed to determine experimentally whether such biochemical intervention offers real advantages in protection of acutely ischemic myocardium Two major questions are addressed (1) does intravenous administration of FDP stimulate glycolysis and improve energy production and mechanical function of ischemic myocardium and (2) will this metabolic intervention result in practical benefit and have eventual application in modifying the extent of the ischemic injury in the heart muscle?

Methods

Twenty five mongrel dogs* were used in this study After sedation with morphine sulfate 15 mg (subcutaneous) general anesthesia was induced with pentobarbital 30 mg/kg given intravenously The animals were secured in the left lateral decubitus position intubated and ventilated with a respiratory pump with the use of ambient air Both carotid and jugular veins were dissected free and were used to place catheters under fluoroscopic guidance into the left ventricle pulmonary artery left anterior descending (LAD) or circumflex (CFX) artery and right atrium Another catheter was advanced through a femoral artery to the aortic root while

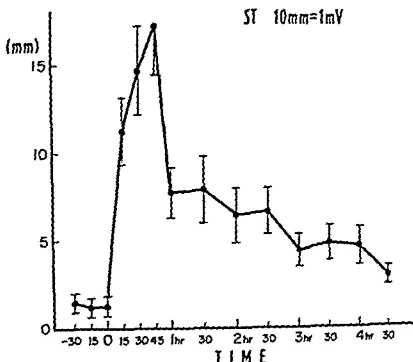

Fig 3 Precordial ST-segment elevation after coronary occlusion and the effect of FDP intravenous administration which began at 45 minutes after the onset of ischemia Values shown are means ± SE (10 dogs)

myocardium were also analyzed for cytochrome oxidase (cyt a_3)[19] and lactate dehydrogenase activity [20]

In five normal anesthetized animals FDP was given intravenously in doses ranging from 100 mg to 2 gm./kg (from 20% stock solution) in order to verify whether this compound has any hemodynamic effects In two animals we studied the ATP and CP in the heart and other organs while in the remainder we studied not only hemodynamic parameters but the plasma half life of FDP and blood lactic acid concentration as well. Also the effect of FDP on the dog erythrocyte metabolism both in vivo and in vitro was assessed This consisted of measuring the ATP and 2 3 DPG content of the erythrocytes and comparing the contents to those that were incubated with glucose

Results

Hemodynamics Occlusion of one of the major branches of the left coronary artery resulted in a drop in mean arterial pressure and left ventricle systolic pressure while the left ventricular end diastolic pressure (LVEDP) began to rise progressively (Figs 1 and 2) The cardiac output also decreased significantly from 4 86 ± 0.56 L/minute to 2 77 ± 0 2 L minute during the ischemic period. Within 7 to 11 minutes after the intravenous administration of FDP the LVEDP began decline from 13.82 ± 3.3 mm Hg and stab[illegible] 6.8 ± 2 0 mm Hg until the termination of [illegible] experiment (Fig 2) The FDP administration caused the left ventricular and aortic pressures rise but they never reached control level (Fig [illegible] The same trend was exhibited by the dp/dt (F[illegible] 1) The negative dp/dt reflected the relaxa[illegible] phase which also improved after the FDP a[illegible] istration The cardiac output after the F[illegible] administration began to increase progress[illegible] and in about 15 to 20 minutes after the admin[illegible] tration of FDP it attained a value of 4.4 ± [illegible] L/minute and remained there until the term[illegible] tion of the experiment The [85]Kr clearance [illegible] the ischemic region in the closed-chest a[illegible] was 11.82 ± 1 6 ml/min/100 gm., while the c[illegible] trol flows were in the range of 104 ± 34 [illegible] min/100 gm By the end of the fourth ho[illegible] [85]Kr clearance increased to 19.36 ± 2.1 ml [illegible] 100 gm. Of the 10 control animals, three [illegible] lated and two had no significant hemodynamic [illegible] ECG changes In the rest the mechanical [illegible] tion of the heart deteriorated progressively

Effect of FDP on ECG In some of the co[illegible] and treated closed-chest animals there was [illegible] elevation of the ST segment prior to occlu[illegible] We attributed this ST segment elevation [illegible]

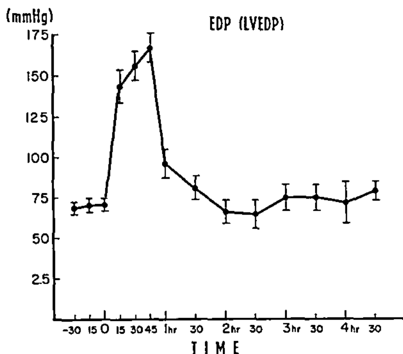

Fig 2 The time response of left ventricular end diastolic pressure *(LVEDP)* to intravenous administration of FDP in 10 dogs with acute myocardial ischemia The FDP administration began at 45 minutes after the onset of ischemia The most pronounced decline of LVEDP was observed during the first 15 minutes after the FDP was given

bolus of lidocaine only during the 45 minute period After FDP or glucose administration had been started (i e at 45 minutes) no drugs were given except for a maintenance dose of anesthetic During this period cardiac output measurements using the thermodilution technique were made at 0 minutes 20 minutes 30 minutes and at 45 minutes and concurrently the other hemodynamic and electrophysiological data were recorded In the closed chest group the coronary blood flow measurements were made 1 minute prior to occlusion and at 30 minutes of ischemia

Ischemia + FDP intervention At 45 minutes of ischemia administration of FDP was started via the femoral vein using a Harvard infusion pump at the rate of 1 25 mg/min/kg A stock solution of 5% FDP prepared 30 minutes prior to administration from fructose 1 6 diphosphate sodium salt (Sigma Chemical Co chemical grade III) was stored in a refrigerator The control animals (10) received 5% dextrose in water at the same rate For the next 4 hours (i e 4 hr and 45 minutes after onset of ischemia) both the treated and control animals received only FDP and glucose at precisely specified concentrations and rates During this period [85]Kr clearance determinations from the ischemic region were made every 30 minutes while hemodynamic and electrophysiological parameters were monitored constantly on a DR 8 Electronics for Medicine recorder Recordings of these data were made every 15 minutes cardiac output determinations were made every 30 minutes At the conclusion of each study (4 hr and 45 minutes) or following ventricular fibrillation the chest was opened and transmural sections from the ischemic and normally perfused myocardium were taken with a specially designed cutting tool that had been cooled in liquid nitrogen These myocardial tissue samples were used for ATP CP lactate and histochemical studies

The frozen transmural sections of both normally perfused and ischemic myocardium were homogenized in 6% perchloric acid and the supernatant was used to determine ATP CP and lactate tissue content The ATP and CP were assayed with the method described by Lamprecht and co workers[16, 17] and the tissue lactate was assayed by the method of Marbach and Weil[8] Sections from ischemic and normally perfused

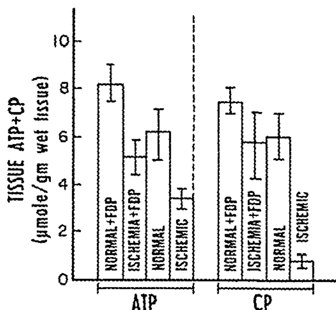

Fig 5 Effects of fructose 1 6 diphosphate *(FDP)* on high energy phosphates in the normally perfused and ischemic myocardium (10 dogs) The effects of FDP on myocardial tissue content of adenosine triphosphate *(ATP)* and creatine phosphate *(CP)* are compared to the control group that received equimolar dextrose (labelled *normal* and *ischemic*) Each column represents the *mean* ± SD

normal and ischemic myocardium (before cytolysis occurs) (2) as a means of indirectly monitoring the oxygen deficit in the ischemic myocardium demonstrated by the low activity of the reduced form of cyt a_3 Histochemically, the activity of cyt a in ischemic tissue was very diminished in both treated and untreated animals (except for the two control dogs that had no hemodynamic nor ECG changes) while LDH activity appeared the same for both groups

The effect of FDP in normal animals In five normal anesthetized dogs the plasma half life was found to be 18 53 ± 1 62 minutes The disappearance rate of FDP when added to dog blood at 37° C was 76% less than when FDP was administered intravenously This indicates that approximately 24% is taken up by the erythrocytes and hydrolyzed prior to being taken up by the different tissues The ATP content of the erythrocytes in the blood incubated for 30 minutes at 37° C was two times higher compared to those that were incubated with equimolar glucose The 2 3 DPG concentration in erythrocytes in vivo and in vitro studies was elevated to the same degree as observed for the ATP Intravenous administration of a total of 500 mg kg over 10 minutes in three anesthetized dogs caused the plasma lactic acid to double within one hour (from 6.21 ± … mg% to 12 8 ± 1 98 mg%) while in most tissues including the heart the ATP and CP content were elevated

Discussion

The glycolytic flux in acute myocardial ischemia in the dog is increased ten to fifteen fold during the transition from aerobic to anaerobic energy production [21, 22] This can supply up to 6% of the energy needs of the ischemic mass Phosphofructokinase activity appears to be rate limiting for glycolysis as shown by the accumulation of glucose 6 phosphate and fructose-6-phosphate [1, 2] Fructose 1 6 diphosphate (FDP) is an intermediate substrate in glycolysis Its depletion in the course of acute ischemia is due to the inactivation of the highly pH sensitive enzyme phosphofructokinase (PFK) which many investigators [14, 15, 23, 24] have attributed to failure of glycolysis to proceed in such conditions The low activity of PFK can be best explained by its properties Kubler and Spieckermann [1] have shown that the activity of PFK is less restricted in experiments with cardioplegia and anoxic perfusion than in ischemic cardiac arrest where lactate production is very slow This implies that PFK is a highly pH dependent enzyme (conclusion similar to that of Mansour [25]) The metabolic acidosis that has taken place inhibits the PFK however when the lactic acid has been washed out from the myocardium and acidosis is corrected Kubler and Spieckermann [1] have observed reactivation of PFK The studies of Mansour on heart phosphofructokinase also confirm that PFK is highly sensitive to acid pH At the very late stage of ischemia glycolysis is again a function of PFK activity simply because there is not enough ATP for phosphorylation of fructose 1 6 diphosphate although there is increased concentration of glucose 6 phosphate and fructose 6 phosphate

As PFK appears to be the limiting step in anaerobic glycolysis the hexokinase and the phosphorylase are of no interest if FDP is the initial step but phosphoglyceraldehyde 3 phosphate dehydrogenase needs a constant supply of NAD to function In ischemic conditions when glucose is the substrate there is conversion accumulation of NADH due to the decreased activity of PFK rather than of pyruvate kinase (PK) It is very important to note that pyruvate

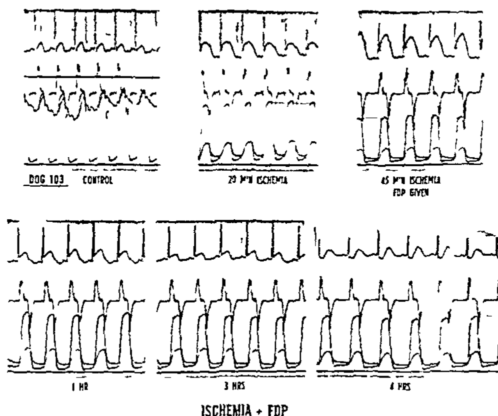

Fig 4 Representative tracing of the electrocardiographic hemodynamic changes in the closed-chest induced acute myocardial ischemia. On the tracing are recorded the precordial ECG left ventricular pressures, dp/dt and peripheral coronary pressure Note the regression of ST segments after the FDP intervention (pressure calibration is 1 mm. = 1 mm. Hg)

he control period to partial coronary artery obstruction by the Swan Ganz catheter (Fig 3) Once the balloon was inflated or the LAD ligated the ST segment began to rise until FDP was given Within 5 to 7 minutes after the administration of the FDP the ST segment began to decline initially very rapidly for about 20 minutes but later it was less pronounced (Figs 3 and 4) Three of the dogs of the control group (10) that received 5% dextrose in water fibrillated (at 1 hr and 14 minutes 1 hr and 32 minutes and at 2 hr and 46 minutes) In five of these animals the precordial ECG demonstrated progressively increasing myocardial injury while in two dogs of the same group only depression of the ST segment was noted after ligation of the LAD After FDP administration began no arrhythmias were observed in any of the treated animals

Effect of FDP on ATP CP and lactate in ischemic and normally perfused myocardium The ATP content in the ischemic muscle segment of the non treated animals showed about 50 to 60% deficit while creatine phosphate (CP) was very low The absolute values of myocardial tissue content of ATP CP and lactate are given in Fig 5 One may notice that in normally perfused myocardium in dogs treated with FDP there was also a noticeable increase in ATP and CP (Fig 5) The tissue lactic acid in the group that received FDP was higher in the normally perfused myocardium than that found in the group that received 5% dextrose in water (Fig 6)

This difference in tissue lactic acid content found in the ischemic muscle in the treated animals was double that found in the ischemic muscle segment of the controls (Fig. 6)

Histochemical results Although these results are not quantitative and do not influence to a great extent the conclusion of this study they were used for the following reasons: (1) in ischemic myocardium the cytoc (cyt a) activity is very low while dehydrogenase (LDH) levels are t

dium These results indicate that FDP intervenes in the Embden Meyerhof pathway not only as a high energy substrate but also as a metabolic regulator influencing the activity of phosphofructokinase and that of pyruvate kinase FDP also stimulates glycolysis in dog erythrocytes and increases their ATP and 2 3 DPG content by a factor of 2

The most significant finding in these studies is that this biochemical intervention appears to restore the depressed activity of glycolysis in ischemic myocardium

kinase needs FDP as an allosteric cofactor which directly stimulates its activity This influence of FDP on pyruvate kinase activity has been observed in the liver[25] developing embryo and in yeast[27, 28] When PFK is activated there is no available FDP which is needed for the PK to operate at optimal reaction velocity for the production of pyruvate hence no substrate for lactate dehydrogenase to generate NAD There fore it appears that the presence of FDP is necessary not only as a substrate but as a metabolic regulator in order for the glycolysis to function at the level of the trioses

Another important catalytic activity of FDP is its direct feedback action on phosphofructokinase (PFK) The activity of PFK is stimulated by ADP AMP and inhibited by ATP citrate[3] and acidosis FDP in high concentration removes this inhibition of ATP citrate and acidosis This has been shown in this study and indirectly supported by the fact that the FDP administra tion in man induces lactic acid increase and increased glucose utilization[31, 3] Theoretically such an increase in ATP/ADP ratio induced by the FDP disinhibition of PFK could be main tained as long as an excess of FDP exists in cytosol in both normally perfused or ischemic tissue (provided that there is still some residual flow) The other advantage of using FDP as a substrate in acute ischemia and any energy defi cient states is obvious the rate limiting enzymes above PFK are eliminated and those below are no longer inhibited From an energetic point of view the advantage of using FDP as the initial sub strate for glycolysis is that the net yield of the anaerobic metabolism of one mole of glucose is 2 ATP while if one mole of FDP is metabolized in the same conditions it will produce 4 ATP because there is no phosphorylation of glucose and fructose 6 phosphate reactions which re quire utilization of ATP On the other hand while doubling the quantity of ATP produced lactate production remains the same as though one mole of glucose had been metabolized It is obvious that in order to obtain the same results in the direction of making usable energy available from FDP it is necessary to administer it in large quantities (on the order of several grams) (The LD_{50} of FDP when administered at the rate of 500 mg /minute in dogs is approximately 5 8 to 6 gm /kg)

Another important finding in this study is that

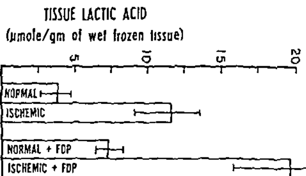

Fig 6 The mean myocardial tissue lactate content in the normally perfused ischemic myocardium for the group that received 5% dextrose in water (the two columns on the *left*) and the group that was treated with fructose 1 6-diphosphate *(FDP)* on the *right* Note that the value for ischemic myocar dium from the dogs that received FDP is almost double that found in the controls

FDP causes a substantial increase of 2 3 DPG in the erythrocytes This increase of 2 3 DPG is of importance for the oxygen exchange between hemoglobin and tissue It also contributes per haps in a lesser manner by increasing the oxygen available to the marginal heart muscle surround ing the ischemic tissue

The results of this study demonstrate that FDP when given to dogs with experimentally induced acute regional myocardial ischemia improves the mechanical function of the heart causes regression of electrocardiographic ischemic changes and increases significantly the ATP and creatine phosphate in both ischemic and normal ly perfused myocardium Extrapolating from these results it appears that FDP can indeed restore the depressed activity of the Embden Meyerhof pathway in ischemic myocardium

These conclusions suggest a rational basis for employing FDP in clinical situations as an agent to limit or decrease infarct size in acute myocar dial infarction

Summary

The hemodynamic electrocardiographic and metabolic responses of dogs with acute myocar dial ischemia to intravenous administration of fructose 1 6-diphosphate (FDP) were assessed

Analysis of the results (compared to dextrose control) revealed evidence of major improvement of LVEDP and cardiac output significant decrease of the ST segment and large increases of ATP and CP in the ischemic district and to a lesser degree in the normally perfused myocar

before the induction of ischemia the balloon was inflated with 1 ml of air and peripheral coronary pressure was monitored using a Statham strain gauge Complete coronary occlusion was evidenced by a reduction of mean peripheral coronary pressure to approximately 30 mm Hg and by the appearance of an injury potential on standard Lead I No antiarrhythmic drugs were used and animals that fibrillated within the initial 15 minute high risk period were excluded from the study Thus four animals of the non treated group three of the indomethacin treated group and one of the aspirin treated group were excluded from the study These eight animals were not included in the group of 76 animals shown in Table I The experiment was designed for a four hour ischemic period during which hemodynamic parameters and electrocardiograms were continuously monitored and were intermittently recorded along with cardiac output Estimated size of the ischemic area was made during the four hour period from 20 precordial ECG leads determining the number with ST elevation (N ST) and the sum of the ST elevation (ΣST) using an electrical calibration of 0 1 mV[9] Serial arterial blood samples were taken from both groups for the plasma free fatty acid determination method As described before [1, 11] microcirculatory thrombosis was determined at the end of the four hour balloon occlusion by taking multiple myocardial tissue samples from the region of the obstructed coronary artery and the contralateral non ischemic area from animals preinfused with [5]Cr or [11]In Microcirculatory thrombosis was expressed as the radioactivity ratio of the multiple tissue samples taken from the ischemic and non ischemic areas

Chronic use of aspirin versus indomethacin during non-thrombotic myocardial ischemia effects on survival

Christos B Moschos M D
Bunyad Haider M D
Amparo J Escobinas B S
Ashwinkumar Gandhi M S
Timothy J Regan M D
Newark N J

Our previous studies on the effects of chronic treatment of aspirin (ASA) upon acute non thrombotic coronary occlusion in dogs showed that this analgesic was effective in significantly decreasing the incidence of ventricular fibrillation associated with a reduction of sodium and water accumulation and potassium loss in ischemic tissue[1] On the other hand recent reports on indomethacin an analgesic with action upon platelet function and prostaglandin metabolism described as similar to that of ASA[2,3] showed that when given acutely ischemia induced by coronary ligation was enhanced [3] In view of this disparity as well as other differences related to the regulation of myocardial blood flow[5] we have utilized a closed chest canine model to study the effects of chronic treatment with indomethacin upon arrhythmias during non thrombotic coronary occlusion and compare its effectiveness with that of ASA

Methods

A total of 76 apparently healthy male mongrel dogs weighing 20 to 26 kilograms were used and were divided into two groups Group A (N = 20) treated with aspirin 600 mg daily and Group B (N = 20) treated with indomethacin 25 mg /day The doses of the two drugs are moderate therapeutic schedules calculated on the basis of body weight Both groups were treated for seven consecutive days prior to the day of the experiments A group of 36 dogs served as non treated controls After an 18 hour fast all animals on the day of the experiment were anesthetized with morphine sulfate (3 mg /kg intramuscularly) and sodium pentobarbital (20 mg /kg intravenously) and were subsequently placed on a respiratory pump to maintain adequate ventilation Frequent pH determinations were performed to confirm maintenance within the physiologic range The left jugular vein and left and right carotid arteries were exposed through small skin incisions Number 8F catheters were passed into the left ventricle via the right carotid artery and the root of the aorta via the femoral artery Left ventricular and aortic pressures were recorded by means of Statham strain gauge transducers using an Electronics for Medicine DR 8 amplifier recorder Cardiac output was determined by the thermodilution technique with the thermodilution catheter placed in the main pulmonary artery via the jugular vein[6] All animals were under continuous electrocardiographic monitoring

Myocardial ischemia was induced by means of a double lumen balloon tipped catheter inserted through the left carotid artery and positioned under fluoroscopic control in the left anterior descending coronary artery approximately 2 5 cm from its origin as described before[1] After determining control hemodynamic parameters

when compared to both the non treated group and the indomethacin treated group ($P < 0.02$) Table VII shows radioactivity from labelled platelets in tissue samples from the ischemic and non ischemic areas indicating that only when thrombus was obstructing the left anterior descending coronary artery was there significant accumulation of platelets in the microcirculation, suggested by the significant ratio of ischemic to non ischemic tissue With balloon obstruction there were no differences when compared to non treated or to aspirin treated animals

Discussion

The results of the study suggest that in the absence of a thrombotic process in the coronary arteries aspirin pretreatment appears to be capable of modifying survival associated with balloon obstruction of the coronary artery In contrast, pretreatment with indomethacin failed to reduce mortality rate which was the same as the one observed in the non treated animals Analysis of the data obtained in the study indicates that whereas the hemodynamic changes were not consistent among the three groups myocardial injury following balloon occlusion appeared to be of lower magnitude in the aspirin group at the end of the four hour period when compared to its own control Since water and cation changes after four hours of ischemia were less extensive in the aspirin group one could postulate on the contribution of more extensive tissue swelling in the non treated as well as in the indomethacin treated group contributing to local changes generating more intensive ischemia and higher incidence of fatal arrhythmias

It should be noted that loss of potassium in the indomethacin group was the smallest among the three groups Since in studies by others [illegible] shown that in the animals receiving indomethacin regional and collateral blood flow [illegible] decreased the observed decrease in pota[illegible] loss in the indomethacin group could be a [illegible] related phenomenon A lower perfusion [illegible] could result in a greater accumulation of K [illegible] leaked from the cardiac cell in the interstit[illegible]

This study raises the question regarding the mode of action of the antiplatelet agents, at the cyclo oxygenase level, namely whether the action is indeed non selective affecting indiscr[illegible] inately the enzyme responsible for the genera[illegible] of the opposing prostaglandins stored in pla[illegible] and the vascular endothelium Recent [illegible] suggest that aspirin in small amounts block[illegible] preferentially platelet cyclo oxygenase and the[illegible] fore the generation of thromboxane-A [illegible] allowing its counterpart prostacyclin stored [illegible] the vascular endothelium to exert its vasod[illegible] ing and platelet antiaggregating effect.[illegible] action was also implied by the studies of Cap[illegible] and colleagues[14] who found that aspirin pre[illegible] ment increased collateral flow after co[illegible] occlusion in dogs[14] In the studies of Korb[illegible] Moncada[13] it was found that aspirin in do[illegible] 150 mg/kg blocked both platelet and endoth[illegible] prostaglandin However using 10 mg/kg th[illegible] investigators described a net effect in fa[illegible] prostacyclin [illegible] The results obtained in our [illegible] could be relevant to the observation made [illegible] Korbut and Moncada with their lower a[illegible] dose since the dose of 30 mg/kg, although [illegible] than 10 mg/kg is still within the usual th[illegible]

nary occlusion in the treated and non treated animals (Table II) aortic pressure in the indomethacin treated group appears to be at levels suggestive of hypertension a described side effect of indomethacin Subsequently over the four hour period systemic pressure fell with a concomitant rise in the left ventricular end diastolic pressure to levels that were significant when compared to control In contrast pressure changes in the non treated and aspirin treated groups were less consistent showing a significant end diastolic pressure rise in the aspirin group and a significant decrease in stroke volume in the non treated group There were no significant changes in heart rate among treated and non treated groups Precordial ECG mapping (Table III) showed that the degree of ischemia over the four hour period of observation remained practically unchanged from the non treated and the indomethacin treated animals whereas in the aspirin group there was a gradual decrease in the extent of ischemia although the observed differences were not statistically significant

Table IV shows changes in water content and electrolyte concentrations in the ischemic cardiac tissue In the aspirin treated group water accumulation was significantly less in all layers when compared to the non treated group In the indomethacin group the increased tissue water was somewhat less than in the non treated group but more than in the aspirin treated group in the inner and middle layers Sodium increments were of smaller magnitude in the aspirin treated group statistically significantly different from the non treated animals in the outer and mid layers In the indomethacin group the gain of sodium was consistently more in all three layers However while potassium loss from ischemic tissue was reduced in the aspirin group particularly in the endocardial layers it was even more so in the indomethacin group when compared to the non treated group Free fatty acid determination in all groups showed that the expected rise in FFA in ischemia was aborted in the aspirin as well as the indomethacin treated animals (Table V)

Comparing mortality rates in the three groups (Table VI) it was found that in the aspirin treated group mortality rate was significantly less

sodium and water abnormalities of the ischemic tissue These changes were not related to consistent abnormalities in hemodynamic parameters or evidence of microcirculatory thrombosis

Summary

In view of the reported disparity of the effects upon ischemic myocardium of aspirin and indomethacin both affecting platelet function and prostaglandin metabolism we utilized a closed chest canine model to study the effects of chronic treatment with these agents upon arrhythmias during non thrombotic coronary occlusion Group A (N = 20) and Group B (N = 20) were pretreated for seven consecutive days with aspirin 600 mg /day and with indomethacin 25 mg /day respectively A group of 36 non treated animals served as controls Determination of hemodynamics revealed no significant differences in left ventricular function among the various groups although blood pressure levels were consistently higher in Group B Precordial ECG mapping showed lower magnitude of myocardial ischemia in the aspirin group Changes in water and cation composition of the ischemic tissue after four hours of coronary occlusion were also significantly lower in the aspirin group suggesting that more extensive tissue swelling in the indomethacin group might have contributed by means of more intensive ischemia to a higher incidence of ventricular fibrillation Consistently higher blood pressure levels requiring increased mechanical demands on the myocardium would enhance the negative results observed in the indomethacin group Mortality rate was 5% for the aspirin group versus 40% and 39% for the indomethacin and the non treated groups respectively ($P < 0.015$) The failure to observe significant platelet accumulation by radioactivity counts in either treated or non treated animals using [51]Cr and [111]In labelled platelet indicated that microcirculatory thrombosis was not a feature in this model It is not clear to what extent the reported diverse mostly inhibitory effects upon the various enzyme systems and lysosomal membrane ascribed to anti inflammatory agents are applicable more for indomethacin per se or for the therapeutic schedule used in this study in order to explain its different effect upon ischemic myocardium

peutic levels and much closer to them than the dose of 150 mg /kg These observations are consistent with previous studies describing differences in the effect of aspirin and indomethacin upon platelet prostaglandin synthetase It was found that aspirin induced a long lasting or irreversible inhibition of platelet prostaglandin synthetase whereas *indomethacin inhibited the enzyme for* only a short period of time which might have expectedly cancelled a favorable effect of a non antagonized endothelial prostacyclin such as described for aspirin [13 15] These findings then could explain at least in part the beneficial effect observed in the aspirin treated group and the negative results observed in our indomethacin treated animals which were consistent with observations indicating the adverse effect of this prostaglandin inhibitor upon ischemic myocardium [5] Since the *absolute level of blood pressure* in the indomethacin treated animals was higher than that of the other groups the adverse effect of this parameter requiring increased mechanical demands on the myocardium will have to be also considered in explaining the negative results observed in the indomethacin group Moreover it has been pointed out that prostaglandin inhibitors exert with plasma levels achieved with therapeutic doses such as used in our study inhibitory effect upon a variety of other enzymes and cellular systems Among anti inflammatory agents indomethacin used as a reference compound was documented as affecting a host of enzymes [8] and in addition to inhibiting prostaglandin synthetase was also described as blocking membrane transport of prostaglandins and therefore access to their *environment* and *interference with pro*tection of ischemic myocardium Whether such inhibitory activity is more consistent among the other inhibitors for indomethacin per se at the doses given in our studies is not clear However

its reported diverse effects upon the various enzyme systems and lysosomal membrane could render the observed unfavorable effects of indomethacin upon ischemic myocardium plausible It is worth noting that in most of the experimental studies with indomethacin the compound was administered to open chested or preinstrumented animals and the doses used were far in excess of suggested therapeutic levels per weight unit In contrast the results in our studies were obtained by long term daily administration of indomethacin at conventional therapeutic doses in animals that remained intact throughout the treatment and experimental period

The failure to observe significant platelet accumulation by radioactivity counts in either treated or non treated animals using ^{51}Cr or ^{111}In indicated that microcirculatory thrombosis is not the issue in this model.

The aborted free fatty acid rise in both treated groups might also be discounted in explaining mortality rate differences among the treated groups Presently the exact mode of action of the *anti inflammatory agents in this model* and this species eludes a clear understanding It appears then that pretreatment with relatively low dose of aspirin was accompanied by lower incidence of ventricular fibrillation and by lower degree of

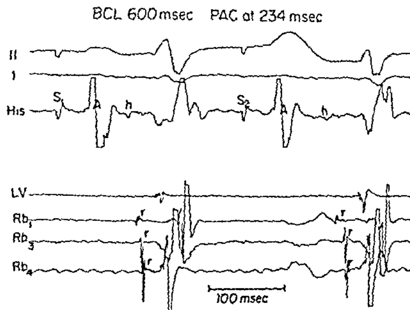

Fig 1 This figure shows the last of nine depolarizations that resulted from right atrial drive at 600 msec basic cycle length and also the depolarization produced by premature right atrial drive at 234 msec. Electrograms (from top to bottom) II and I represent electrocardiograms from ECG Leads II and I His represents the recordin from a His bundle catheter inserted into the aortic root Deflection S_1 is the stimulus artifact A is the atrial depolarization h is the His bundle activation which is followed in turn by the activation of the high septal myocardium and S_2 is the second and premature stimulus artifact. LV electrogram is recorded from bipolar electrodes in the left ventricular apex and shows some Purkinje activation and activation time of the left ve [illegible] Rb, electrogram shows the activation of the proximal right bundle (r) followed by activation of the underlying right ventricular septum Rb_3 represents an electrogram 6 mm more distal on the right bundle showing right bundle activation (r) and mid right septal activation Pb_4 represents the right bundle activation 9 mm more distal from the Rb electrode The second complex is premature and shows conduction delay above the His bundle (increased A H interval) and conduction delay in the proximal right bundle branch of 15 msec.

the proximal right bundle as it emerged onto the surface of the right ventricular septum A typical example of the activation sequence of a normal and premature beat is shown in Fig 1 The first complex shown represents the response to the last of nine regular stimuli given at 600 msec cycle lengths Note that the His bundle activation is quickly followed by activation of the proximal right bundle branch (electrode Rb) and then at electrodes 6 and 9 mm more distal (Rb_3 and Rb) The muscle activation can be seen to occur earliest in the more distal right bundle electrodes and later near the proximal right bundle electrodes located in the upper right ventricular septum The time of activation of both the right and left ventricular endocardium is nearly simultaneous The second complex of Fig 1 is the least premature impulse that would not produce FRBBB Note the similar activation of the second complex sequence to the first complex and compare the delay of conduction that occurs in the proximal right bundle branch between e[illegible] trodes Rb, and Rb, The degree of con[illegible] delay shown here is the maximum attai[illegible] nine experiments before blockage of cond[illegible] would occur

Fig 2 shows the effect of making the prem[illegible] stimuli more premature by only 4 msec [illegible] same animal The activation sequence [illegible] quite different in the second complex [illegible] the FRBBB There is no apparent activat[illegible] the right bundle distal to the most prox[illegible] electrode The activation of the right ventr[illegible] myocardium now lags behind that of the [illegible] ventricle consistent with the delay of activ[illegible] of the right ventricle In these experiments, [illegible] visualization of the activation front as rec[illegible] by the electrodes was never noted witho[illegible] seeing delay in activation of the right ventr[illegible] myocardium In every instance of FRBBB [illegible] duced in each of the nine experiments, the [illegible] loss of recording of right bundle activ[illegible]

Site of functional right bundle branch block

Chalmers Lyons M D F.A C C
Salt Lake City Utah and Albany N Y

There has been considerable speculation as to the site and mechanism of functional right bundle branch block (FRBBB) Certain investigators believe that the site of conduction block is at the distal end of the right bundle while other workers favor a more proximal site[5 11] The present work was undertaken to document the site of functional right bundle branch by placing a 36 electrode plaque directly over the right bundle branch in an in vivo canine heart preparation and then recording the activation potentials both during normal conduction and during FRBBB

Methods

Acute experiments were performed in nine mongrel dogs weighing 15 to 30 kilograms anesthetized with 30 mg /kg of phenobarbital Artificial ventilation was maintained according to the Kleinman and Radford nomogram[1] with a Harvard ventilator A thermal blanket was used to maintain body temperature Arterial and venous pressures were monitored throughout the experiment and volume replacement was given to maintain physiologic blood pressures The heart was exposed by a midline sternal incision and the animal was anticoagulated with 10 000 units of heparin The right heart was bypassed by collecting superior and inferior vena caval blood flow into a cardiotomy reservoir and pumping this blood with a roller pump through a blood filter and then into the pulmonary artery A more detailed description of this preparation is described elsewhere[13] With the heart empty of blood a 2 to 3 cm incision was made into the anterior right ventricular wall to expose the septum and the right bundle branch A 10 by 15 mm plaque with 36 stainless steel flush electrodes was then sutured over the right bundle The poles of the electrodes were separated by 1 5 mm across and 3 mm vertically The plaque was positioned just lateral and inferior to the papillary muscle that inserts into the pulmonary conus and was superior and medial to the anterior papillary muscle Up to six simultaneous bipolar electrograms could be monitored down the length of the right bundle at 3 mm intervals After electrode placement the incision in the right ventricular wall was closed and the right heart bypass system was discontinued Right bundle and His electrograms were recorded with a frequency response of 50 to 2 000 Hz ECG leads were recorded at 0 2 to 2 000 Hz Recordings were made on a light beam oscillograph at paper speeds of 25 to 200 cm /sec The sinus node was crushed to allow for slower spontaneous heart rates Driving and premature stimuli were of 2 msec duration and 1 5 times threshold in intensity to the right atrium via bipolar hook electrodes At the termination of each experiment the location of the electrodes were confirmed by staining of the specialized conduction system with iodine solution

Results

FRBBB was produced in nine dogs with high quality recordings from the right bundle branch by the 36-electrode plaque In every case of FRBBB produced the conduction block was found to be located within the first 5 to 6 mm of

hypoxic may play a role The change in right bundle size as compared to the left bundle may result in loss of summation effects on conduction

Summary

An in vivo canine heart was prepared by utilizing a temporary right heart bypass system to place close bipolar electrodes along the course of the right bundle branch Activation within the right bundle could be recorded in up to six locations along the right bundle with premature supraventricular stimulation that caused functional right bundle branch block The loss of activation recordings was found to occur in the proximal 0 to 6 mm of the right bundle branch in every instance and in nine different preparations

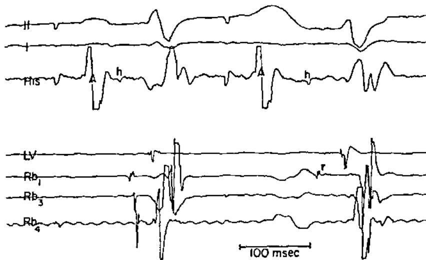

Fig 2 Electrograms are labeled similar to those in *Fig 1* from the same experiment only 1 or 2 minutes later The premature stimulus artifact is now 4 msec more premature There is now functional right bundle branch block with block of activation beyond the most proximal right bundle branch electrode There is delay of activation of the right muscle (compare activation time of right and left ventricular myocardium)

occurred in the proximal portion of the right bundle branch as it emerges onto the surface of the right ventricular septum

Discussion

The occurrence of FRBBB on clinical tracings has generated considerable interest as to the site and mechanism of the conduction block A search for the site of FRBBB has been recently stimulated by the reports of Myerburg and associates[3,4] which utilized an in vitro canine myocardium and showed that the area of the specialized conduction system with the greatest refractoriness was 2 to 3 mm proximal to the Purkinje muscle junction The physiologic role of prolonged refractoriness at the distal specialized conduction system could be consistent with a peripheral conduction block concept Moe and co-workers[5] however have provided indirect evidence suggesting that the site of FRBBB is more proximal Elizari and colleagues were able to show a marked increase in action potential duration in the area of the proximal bundle branches and show slowing of conduction of premature impulses in this area In in vivo canine heart preparations Zipes and associates have shown that the site of block is proximal to the false tendon portion of the right bundle branch Catheter recordings in man [9] and dogs[10] also support a proximal site of FRBBB Our work more precisely documents the site of conduction block to be in the first few mm of the right bundle as it emerges into the right ventricular surface of the septum In none of our experiments was the site of FRBBB located in the middle or distal portions of the right bundle branch Our results also do not lend support to the concept of incomplete right bundle branch block at least in the healthy right bundle with premature stimulation methods The maximum conduction delay prior to complete blockage of conduction was up to 15 msec duration in these studies This is in contrast to the study by Elizari and co workers who noted conduction delays of considerable magnitude using an in vitro preparation The difference in our results may be due to the lack of normal perfusion in their experiments

Our results confirm that the site of FRBBB is in the proximal right bundle branch The possible causes of the conduction block in the proximal right bundle during FRBBB are unknown Several possible mechanisms may be active The change of perfusion from arterial blood to right ventricular cavity blood which is relatively

There has been considerable interest recently concerning the effects of changes in ventricular afterload on the extent of myocardial injury following coronary artery occlusion Experimental studies suggest that a reduction in ventricular afterload by decreasing coronary perfusion pressure increases ischemic damage following coronary artery occlusion However clinical studies report a decrease in the predicted infarct size if in the course of acute myocardial infarction ventricular afterload is reduced Also studies dealing with the effects of combination therapy with nitroglycerin and phenylephrine on the extent of ischemic injury during acute myocardial infarction have been contradictory Thus there appears to be uncertainty regarding the effects of ventricular afterload changes on the extent of myocardial damage following coronary artery occlusion

The methods commonly employed to assess the extent of myocardial injury involve ST segment mapping and serial analysis of serum CPK changes However recent studies suggest that ST segment changes following coronary artery occlusion may not accurately reflect the magnitude of myocardial ischemic damage Also controversy has arisen concerning the reliability of assessing infarct size from serum CPK changes alone Furthermore these methods assess neither left ventricular functional impairment nor functional capacity of the remaining functional myocardium

The present study was undertaken to evaluate the effect of different mean systemic arterial pressure levels on the reduction of left ventricular functional reserve capacity following the insult of coronary artery occlusion Left ventricular functional reserve capacity was assessed by determining the tolerance of the left ventricle to increasing heart rate and to increasing resistance to ventricular ejection Thus the heart rate and the systemic arterial pressure at which mean atrial pressure attained 12 mm Hg was used arbitrarily to define the limits of left ventricular functional reserve capacity

Materials and methods

Mongrel dogs weighing 18 to 38 kilograms were anesthetized with intravenous sodium pentobarbital (30 mg /kg.) Following intubation with a cuffed endotracheal tube the animals were ventilated using a volume respirator (Harvard Apparatus Co Dover Mass) with 97% O and 3% CO_2 and constant minute ventilation throughout each experiment All animals received a continuous intravenous infusion of sodium bicarbonate 0 05 mM min $^{-1}$ kg $^{-1}$ of body weight for prevention of metabolic acidosis Arterial pressure was monitored from the beginning of the study via a No 8 catheter introduced into the left femoral artery

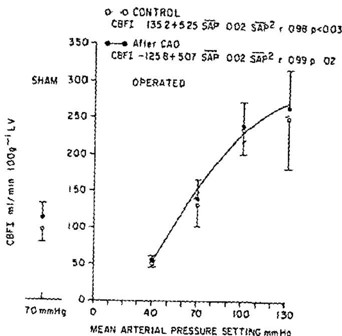

Fig 3 Coronary blood flow index (*CBFI*) changes in response to mean systemic arterial pressure setting before (control) and after coronary artery occlusion (*CAO*) Mean values ± SE for each group of animals (n = 5) Curvilinear relationship of mean values was similar for both conditions

define the lower limits of LVFRC by decreasing $\overline{SAP}$ and HR However when $\overline{SAP}$ was steadily decreased the $\overline{LAP}$ usually decreased in similar fashion Also at slower HR escape ventricular rhythms often intervened preventing substantial decreases in HR Thus data describing the limits of LVFRC for lower $\overline{SAP}$ and HR were not sufficient for statistical analysis

In 25 animals prepared as described control data including assessments of LV functional reserve capacity were obtained Each dog was then randomly assigned to one of five equal groups One group in which $\overline{SAP}$ was maintained at 70 mm Hg served as sham and the coronary artery although similarly prepared was not ligated In the remaining four groups the $\overline{SAP}$ was set at a new level of 40 70 100 or 130 mm Hg After measurement of CBF and MVO_2 at the new pressure setting the previously isolated anterior descending coronary artery was occluded Following coronary occlusion CBF and MVO_2 were determined at 5 minutes 15 minutes and 30 minutes These data were averaged for subsequent statistical evaluation since they did not vary significantly over time After 30 minutes and while the coronary occlusion was maintained the $\overline{SAP}$ was returned to its original control level of 70 mm Hg At this level CBF and MVO[illegible] again determined and LV functional re[illegible] capacity was redetermined by the two techn[illegible] as described

At the end of the experiment the heart [illegible] excised and Evans blue dye was injected [illegible] low pressure into the coronary artery distal to [illegible] ligature Immediately after injection the sta[illegible] LV myocardium was excised and weighed f[illegible] gross estimation of the non perfused LV myo[illegible]dial segment Subsequently the total LV we[illegible] was determined and was used for indexing the [illegible] of the non perfused segment the CBF and MVO_2 thus data obtained both before and a[illegible] CAO were indexed to 100 g of total wet [illegible] myocardium

Statistical analysis was performed using a[illegible] sis of variance for the five groups of data th[illegible] test for paired observations for comparison [illegible] data obtained in each animal before and a[illegible] coronary occlusion and linear or polynom[illegible] regression analysis for estimating regression [illegible] mean data values

Results

There was no significant difference by analy[illegible] of variance in the indexed weight of stained l[illegible] myocardium following actual or sham corona[illegible] ligation (Table I) The mean percent for all [illegible] dogs was 27 6 ± 1 0 of total LV myocardium

MVO_2I ml O_2/min 100 g⁻¹ LV =

2 71 + 0 103 $\overline{SAP}$ mm Hg $r = 0\ 99$ $p < 0\ 00$[illegible]

Coronary blood flow index (CBFI) va[illegible] before and after coronary occlusion did not d[illegible] significantly in any of the experimental gro[illegible] (Table II) CBFI mean values bear a sim[illegible] curvilinear parabolic relationship to the [illegible] both before and after coronary occlusion (Fi[illegible] The predictive quadratic equation derived f[illegible] values is

apex The pressure signal of the catheter tip transducer was matched with the pressure signal obtained via the lumen using a conventional P23Db pressure transducer A No 8 catheter was placed in the left atrium (LA) via the LA appendage and pressure was monitored using a P23Db transducer Zero pressure reference was set at the mid right atrial level for all transducers

A fiberoptic catheter was placed in the proximal coronary sinus via the right atrial appendage and was connected to an In Vivo oximeter (Physio Control Seattle Wash) for continuous monitoring of oxyhemoglobin saturation of coronary sinus blood and for periodic blood sampling

The mean ($\overline{SAP}$) and phasic aortic pressure the left ventricular pressure (LVP) the coronary blood flow (CBF) signal the coronary sinus oxygen saturation ($ScsO_2$) signal a vertical body surface ECG lead and the LV dP/dt were recorded using an oscillographic recorder (Honeywell 1612 Denver Colo) The temperature of the animals as measured directly from the posterior surface of the heart was maintained at 36 8 ± 0 2 C through adjustment of warm water flow through the heat exchanger

The flowmeter signal of coronary blood flow (CBF) was calibrated before each determination by repetitive (five to eight) timed collections (30 seconds) of the continuous siphon drainage of the right ventricle

Blood samples were obtained from the arterial circuit and from the coronary venous drain and were iced immediately for determination of O_2 content by the Van Slyke method [11] The pH pO and pCO_2 of blood samples were determined using the Astrup apparatus The hemoglobin concentration of the samples was also determined Myocardial oxygen consumption (MVO_2) was derived as the product of the CBF and the corresponding arteriovenous oxygen difference and was then indexed to 100 g of total LV myocardium (MVO_2I) Wet LV weight was determined at the conclusion of the experiment after excision of atria along the atrioventricular groove and the right ventricle along its attachment to the interventricular septum

Experimental protocol *Left ventricular functional reserve capacity* (LVFRC) testing was conducted as follows

1 With the HR set at 120 min the resistance of the arterial extracorporeal circuit was gradually increased at a constant rate by tightening the screw clamp thereby increasing the $\overline{SAP}$ until the mean LA pressure ($\overline{LAP}$) rose to at least 14 mm Hg but not more than 16 mm Hg The slope of $\overline{SAP}$ versus $\overline{LAP}$ was then derived by linear regression analysis of corresponding data points and the $\overline{SAP}$ at which the $\overline{LAP}$ attained 12 mm Hg was designated as the pressure limit of the LVFRC

2 With the $\overline{SAP}$ set and maintained at 70 mm Hg the ventricular pacing rate was steadily increased until the $\overline{LAP}$ rose to the above values The slope of the HR versus $\overline{LAP}$ was similarly derived and the HR at which the $\overline{LAP}$ attained 12 mm Hg was designated as the HR limit of the LVFRC

In each experiment attempts were made to

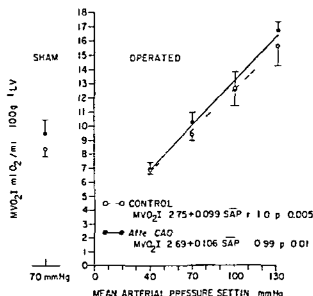

Fig 2 Myocardial O consumption index (MVO I) changes in response to mean systemic arterial pressure setting before (control) and after coronary artery occlusion (*CAO*) Mean values ± SE for each group of animals (n = 5) Linear relationship of mean values was similar for both conditions.

p = Derived by analysis of variance

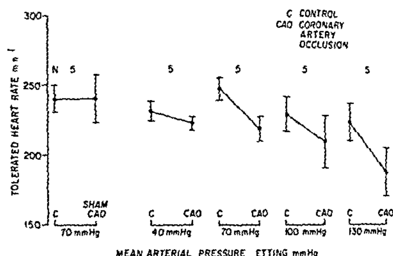

Fig 5 Tolerated heart rate resulting in mean left atrial pressure of 12 mm Hg before (control) and after minutes of coronary artery occlusion (CAO) at the indicated mean systemic arterial pressure setting Tolerated heart rate range after CAO is not significantly affected by the level of pressure setting. However the mean values of tolerated heart rate bear a negative relationship (r = 0 95) to the pressure setting

Before coronary occlusion the results of the control assessment of LV functional reserve capacity as tested by increasing HR, did not differ among the five groups (Fig 5) For all 25 dogs the mean HR at which the $\overline{LAP}$ attained 12 mm Hg was 234.5 ± 4 6 min

Following 30 minutes of coronary occlusion in the four groups with coronary ligation $\overline{LAP}$ of 12 mm Hg was attained during LV functional reserve capacity testing at a HR which was lower than control by an average of 23 1 ± 4 7 min (p < 0 001) (Fig 5) Although the magnitude of this reduction was not significantly different among the four groups by analysis of variance there was a slight trend (0 4 min ¹ per mm Hg) for the mean group values of these post occlusion estimates to correlate negatively with the $\overline{SAP}$ setting of the group In the sham group the results of the control and post sham occlusion evaluations of LV functional reserve capacity by HR did not differ

Discussion

Critique of method The criterion of 12 mm Hg of left atrial pressure for defining the limits of LV functional reserve capacity was set arbitrarily however Braunwald and colleagues[5] reported this to be the upper limit of normal for resting humans Furthermore in these and in similar previous experiments we observed that when $\overline{LAP}$ reaches this level as a result of rapid heart rate systemic arterial pressure increase or coronary artery ligation its rate of rise is abrupt leading to rapid deterioration of ventricular function

We utilized changes in heart rate and arterial pressure to test LV functional reserve capacity because such changes can be controlled independently A similar approach using changes in HR and afterload was used previously by several investigators in both the clinical and experimental setting[16] Quinones and colleagues[6] employed changes in preload in addition to changes in HR and afterload to achieve the same goal

Although it has been adequately demonstrated that after deprivation of blood supply depression of myocardial contractile function occurs within seconds[29,30] the time for retesting LV functional reserve capacity following coronary artery occlusion was set at 30 minutes We elected permanent coronary ligation instead of the coronary occlusion-release model because the latter although probably more sensitive in depicting effects of hemodynamic alterations involves only transient hypoxia We felt pertinent to the purposes of this study that 30 minutes represented sufficient time for the ischemic tissue and vasculature to be affected by the systemic arterial pressure setting with its opposing effects on O_2 supply and demand afforded by the systemic arterial pressure set point either in the direction of preservation of function although not necessarily determining long term tissue viability

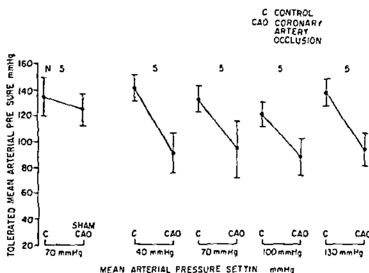

Fig 4 Tolerated mean systemic arterial pressure in mm Hg resultin in mean left atrial pressure of 12 mm Hg before (*control*) and after 30 minutes of coronary artery occlusion (*CAO*) at the indicated mean systemic arterial pressure setting. Tolerated pressure after CAO is not affected by the level of pressure setting

Determined by paired t test

CBFI ml /min 100 g LV =
$-130\,0 + 5\,16\,\overline{SAP}$ mm Hg $- 0\,016\,\overline{SAP}$ mm Hg

or $\overline{SAP}$ within 40 to 100 mm Hg the relationship appears linear and the predictive equation is
CBFI ml /min 100 g LV =
$-70\,2 + 3\,03\,\overline{SAP}$ mm Hg $r = 0\,99$ $p < 0\,001$

Before coronary occlusion control LV functional reserve capacity estimates assessed by increasing aortic root pressure did not differ significantly among the five groups by analysis of variance (Fig 4) For all 25 animals the average $\overline{SAP}$ at which the $\overline{LAP}$ attained 12 mm Hg prior to coronary occlusion was 130 4 ± 6.2 mm Hg After 30 minutes of coronary occlusion in the four groups in which the left anterior interventricular coronary artery was ligated $\overline{LAP}$ of 12 mm Hg was attained during LV testing at a $\overline{SAP}$ level which was significantly lower than control However the magnitude of this reduction in all four groups was similar by analysis of variance averaging 41 9 ± 6 2 mm Hg ($p < 0\,001$) (Fig 4) In the sham group the results of the control and post sham occlusion did not differ

dogs [17 - 23] Nakano[37] reported findings similar to ours in anesthetized dogs but the uncontrolled cardiac output in that study decreased drastically as a result of tachycardia It should be stated however that in preparations with fixed cardiac output stroke volume bears an inverse relationship to HR and according to previous findings from this laboratory the workload imposed on the LV as judged by MVO_2 measurements is about one fifth of that imposed with HR increases at constant stroke volume [38] It is therefore conceivable that different results in conscious dogs may at least in part reflect changes in cardiac output during rapid pacing

With the assumption that loss of LV functional reserve capacity bears a directional although not necessarily linear relationship to the functional loss of myocardium the results of this study clearly indicate that systemic arterial pressure setting does not affect the extent of loss of functioning myocardium following coronary artery occlusion Previous studies using electrophysiological or enzymatic correlates supported mutually opposing views [6] Recently Wyatt and co workers [4] in preparations with left anterior descending stenosis suggested that increasing afterload may have beneficial effects on myocardial metabolism but detrimental effects on ventricular function concluding that ischemic injury may be reduced by increasing arterial pressure but at the expense of LV function Obviously results are bound to vary first according to the degree of stenosis which determines maximal coronary blood flow second according to the level and increment of arterial pressure which determine coronary blood flow and LV work and third according to the oxygenation of arterial blood Our data (Figs 2 and 3) may provide some insight on the effect of systemic arterial pressure changes on the balance of myocardial O supply and demand Arterial pressure bears a linear relationship to MVO_2 but curvilinear to CBF so that for pressure levels above 100 mm Hg the ratio of O supply over demand becomes progressively less favorable The average slope of MVO I increase in response to systemic arterial pressure increments is 0 103 ml O_2 per mm Hg On the other hand for normal blood O_2 carrying capacity of 20 vol % O_2 supply within the 40 to 100 mm Hg pressure range is about three times steeper but above 100 mm Hg tends to plateau towards the MVO I slope Obviously in the presence of coronary stenotic lesio or lower O_2 carrying capacity the O curve will be depressed accordingly Th indicate that an optimal relationship of O to demand relationship occurs at about Hg Increase above as well as decrease be level may have a potentially detrimenta

The reduction of tolerance to tachyca lowing coronary occlusion did not diffe groups with different $\overline{SAP}$ setting How trend toward negative correlation of mea of tolerated HR with $\overline{SAP}$ settin small may warrant further investi both tachycardia [6 41] as well as ischemia result in incomplete myocardial relaxati

The criteria of heart rate and arterial used in this experimental study for estim functional reserve capacity represent th correlates by which survival and degree o ity are ultimately determined Althou term effects may differ it appears acc the results of this study that systemic pressure setting at the early state of ac cardial infarction is not an important nant of functional and probably anatom of myocardium However since mean arterial pressure levels of about 100 afford the best O_2 supply to-demand r pressure level may be optimal for reg compromised perfusion

Summary

The effect of mean systemic arterial ($\overline{SAP}$) on myocardial O_2 consumption coronary blood flow (CBF) and the redi left ventricular (LV) reserve capacity from coronary artery occlusion was stud open chest pentobarbital anesthetized d fixed cardiac output and controlled he (HR) and $\overline{SAP}$ In all animals baseli and CBF were obtained and LV reserve was determined by identifying the HR level which raised mean left atrial pres mm Hg After uniform placement of a nary snare the dogs were randomize equal groups and $\overline{SAP}$ was set at 40 groups) 100 and 130 mm Hg MVO were redetermined and the coronary ar ligated in all except one group (70 mm H served as sham control Thirty minut coronary occlusion MVO CBF and LV capacity were determined again Percent

The basic assumption in this study is that ormally LV functional reserve capacity is a leasure of maximal functioning of all LV seg ients Therefore loss of functional contribution f any of the segments would be reflected as a eduction of the total LV functional reserve revious work supports this rationale although ot necessarily in the sense of a simple mathe iatical relationship[3, 33]

While only one complete sham group for the 70 im Hg pressure setting was provided in this udy other sham experiments performed at both ie 70 and the 130 mm Hg pressure settings iowed that pressure setting did not modify the stimates of LV functional reserve capacity efore or after sham coronary artery occlusions ince the pressure setting alone did not appear to ave an independent effect on LV functional eserve capacity estimates the observed decre ients after coronary artery occlusion were attri uted exclusively to the functional loss of myo ardium Several aspects in the design of this tudy were different from those of previous stud es,[6, 7, 40] and might have contributed to different esults (1) complete coronary occlusion instead f stenosis was utilized (2) left ventricular output ras kept constant rather than allowed to vary in esponse to rate and pressure increases (3) the rterial bypass extracorporeal circuit was proba ly stiffer than the normal arterial tree thereby r higher actual workload to the left ventricle may ave been imposed for comparable mean arterial ressure settings

Discussion of results The grossly estimated ize of non perfused LV myocardium resulting om the coronary artery occlusion was substan ial but uniform among groups This may reflect niformity of occlusion successful randomiza ion but also to some extent the constancy of the ontrolled variables Accordingly differences in V functional reserve capacity among groups ould not be attributed to non uniformity of oronary artery occlusion

Previous work from this laboratory indicated hat left ventricular efficiency does not change fter coronary artery ligations which result in a wide range of sizes of ischemic myocardium[3] In his study constancy of MVO_2 before and after oronary ligation in each group with different ystemic arterial pressure setting implies that fficiency of the intact myocardium also remains onstant at different levels of LV workload The MVO_2 constancy is also indicative of the stability of preparations following coronary occlusion Control MVO_2I values in the sham group were somewhat but not significantly lower than those of the experimental group operated at 70 mm Hg therefore values after sham coronary occlusion appeared higher than sham control

The linear relationship of MVO_2I versus mean systemic arterial pressure setting (Fig 2) was similar before and after coronary occlusion affecting up to 27% of LV mass This further supports the notion that total left ventricular O consumption is proportional to workload and independent of relative size of intact or ischemic myocardium[34] Similar findings supporting the independence of total left ventricular O con sumption from the perfusion or oxygenation con ditions of the myocardium were previously reported in preparations in which MVO_2I require ments were modified by means of heart rate changes before and after coronary occlusion[35]

These findings indicate that for similar work load the reserve capacity of the myocardium is able to compensate for the functional loss of ischemic myocardium without change in O cost In other words left ventricular efficiency remains unchanged at all levels of function although the work per gram of functioning myocardium varies On this basis the extent of functional loss of myocardium cannot be assessed by MVO_2 mea surements as long as the loss is compensated by the functional reserve of the intact part Left ventricular decompensation obviously will occur when the capacity of the intact part to consume O_2 and produce energy is exhausted It follows logically that the larger the size of the remaining intact part the higher the energy demands the ventricle can handle before decompensation Con versely the larger the size of functionally lost tissue the lower the tolerance to increased demands However because of the possibility that the functionally lost tissue not only ceases con tributing but may actually dissipate energy larger infarcts may impinge upon LV functional reserve capacity out of proportion to their size

During the control testing of LV functional reserve capacity $\overline{LAP}$ of 12 mm Hg was attained at the rather low mean systemic arterial pressure level of 130 ± 6 8 mm Hg This level however is in accord with previous reports[35, 3] In regard to heart rate response previous studies reported a lower tolerance of heart rate in intact conscious

erfused myocardium did not differ among groups 27 6 ± 1%) MVO_2 bore a linear relationship to SAP setting whereas CBF bore a curvilinear elationship Coronary occlusion did not modify hese relationships Significant but similar decreases in tolerated HR (23 1 ± 4 7 min) and SAP (41 9 ± 6 2 mm Hg) from control values vere observed in all four groups regardless of SAP etting

We concluded that the impact of coronary igation on MVO CBF the loss of functional *reserve capacity and possibly the extent of* ischemic injury of the left ventricle is not modi ied by afterload changes However optimal O_2 upply to demand ratio appears at SAP of about 00 mm Hg

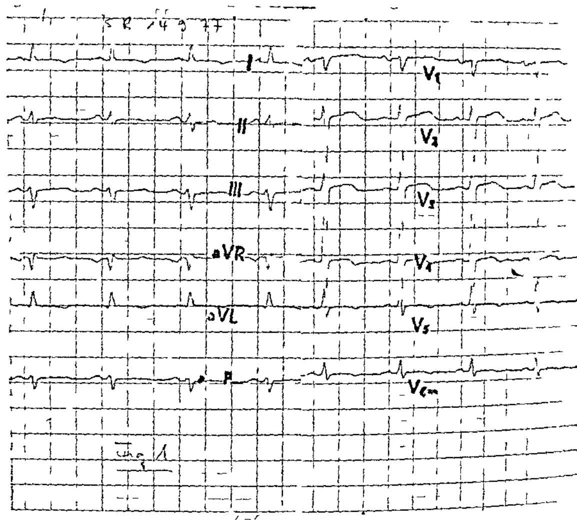

Fig 1 ECG on admission (see text)

dia (104/minute) a distinct pretibial edema enlargement of the heart on percussion splitting of the second heart sound and a soft systolic murmur at the apex on auscultation The blood pressure was 140/80 mm Hg and the jugular venous pressure was not raised

The electrocardiogram (Fig 1) showed a sinus tachycardia marked left axis deviation (greater than −45 degrees) resembling a left anterior hemiblock, minimally el vated convex ST segments terminally negative T waves in Leads I II aV_L and V On x ray (Fig 2) there was a cardiomegaly involving all chambers The heart volume measured by the method of Musshoff and Reindell was 1 030 ml or 15 6 ml/kg weight In addition there were moderate signs of pulmonary congestion The echocardiogram showed enlargement of the left ventricle with diminution of left posterior wall motion There was no pericardial fluid

The results of the laboratory studies are summarized below Erythrocyte sedimentation rate was 103 mm in the first hour white cell count was 9 200/mm plasma thyroxin was 7 1 µg % plasma triiodothyronine was 104 µg % antistreptolysin titre was below 200 I U rheumatoid factor was negative antistreptolysin O reaction 50 U /ml antistreptodornase B was 1 50 antihyaluronidase was 1 < 700 anti NADase was 1 < 50 antistaphylolysin reaction was 1 0 U/ml and CRP was negative Titers for influenza A influenza B param[illegible] Epstein Bar virus and Q fever were negative [illegible] was observed Antinuclear antibodies were not detected

During the course of the disease (Table I) compl[illegible] fixing antibody titers rose from 1 < 16 (one week [illegible] of symptoms) to 1 256 (three weeks after onset) [illegible] virus (CMV) was isolated from the urine taken [illegible] onset of symptoms Specific IgM antibodies were d[illegible] the first serum specimen (first week titer 1 1 024) and [illegible] declined to the end of the third week (1 64)

The technic for the detection of IgM antibodies has be[illegible] described in detail elsewhere[11] the indirect im[illegible] cence method was employed, using CMV infected [illegible] fibroblasts as a source of antigen and fluorescein [illegible] globulin fraction against human µ-chains (d[illegible] rabbit origin)

For the detection of complement fixing antibodies [illegible] extracted antigen (Behring Werke Marburg W Ger[illegible] was used Virus isolation was carried out on human [illegible] cells

After three weeks bed rest the signs of heart [illegible] disappeared On discharge the electrocardiogram [illegible] normal (Fig 3) and the heart volume by [illegible] decreased to 710 ml or 10 6 ml/kg and was [illegible]

Observatıons of alteratıons of the heart ın cytomegalovırus ınfectıon are comparatıvely rare[3 5 5] Wılson Morrıs and Rees de scrıbed a female patıent, aged 60 years wıth a sıgnıfıcant rıse ın cytomegalovırus complement fıxıng antıbody who became ıncreasıngly breath less and had repeated attacks of paroxysmal dyspnea after a head cold which progressed to dry cough and wheezıng On clınıcal examınatıon she was obvıously ıll febrıle (38.2° C) and dyspneıc at rest The jugular venous pressure was raısed 5 cm above the sternal angle There was gallop rhythm wıth pansystolıc and mıd dıastolıc mur murs at the apex and also fıne rales at both lung bases The electrocardıogram showed sınus tachy cardıa left bundle branch block and left ventrıc ular hypertrophy the chest x ray demonstrated cardıomegaly and pulmonary congestıon

Because a cytomegalovırus myocardıtıs ıs rare we felt justıfıed ın reportıng a comparable patıent of our own

Case report

One week before hıs admıssıon to hospıtal, a prevıously healthy man aged 31 years, became progressıvely breathless on effort, needıng to rest after goıng up one flıght of staırs. Moreover he notıced swellıng of hıs ankles and legs. He had nocturıa three tımes each nıght.

Prevıously no cardıac abnormalıtıes had been detected. The patıent presented wıth low grade fever (37.5 C) a tachycar

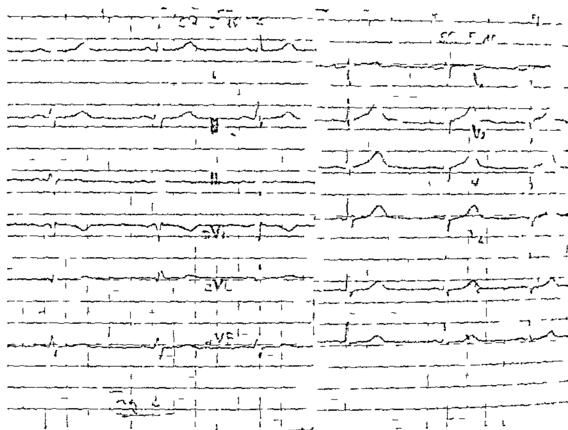

Fig 3 ECG on discharge (see text)

complement fixing antibodies from 1 < 8 to 1 > 64 At necropsy the heart was enlarged and weighed 515 g The microscopic examination showed foci with lymphocytic infiltration and focal fibrosis No inclusion bodies could be seen The pericardial sac contained 180 ml of hemorrhagic fluid so that the question arises whether there was a hemorrhagic tamponade of the heart following the heparin treatment of the coagulopathy

The role of drug treatment of cytomegalovirus infections is unclear Idoxuridine has been effective in infections with the herpes virus[4 52] to which group of viruses the cytomegalovirus also belongs This drug was also used in cytomegalovirus infection with success defined as clinical improvement as well as lowering at the urine content of viruses[6] Floxuridine and 5 fluorodeoxyuridine seemed to have a favorable effect on patients with cytomegalovirus pneumonia and seemed to shorten the clinical course if they were also combined with prednisolone [6] The successful use in generalized herpes infection of cytosine arabinoside hydrochloride[79] a newer antiviral agent led Wilson Morris and Rees[6] to at[illegible] its application in their patient with cytome[illegible] rus myocarditis but only a fall in the [illegible] venous pressure accompanied by a fall in viral titer were observed Their patient has [illegible] remained symptom free on a strict regimen [illegible] persisting gallop rhythm mitral in[illegible] murmur left bundle branch block and ca[illegible] megaly

In view of the many potential toxic side e[illegible] of the above mentioned viricidal drugs t[illegible] probably should be used with restraint and [illegible] conservative means of therapy applied to o[illegible] viral forms of myocarditis such as prolonged [illegible] rest digitalis diuretics etc should be [illegible] considered for these patients

Prophylaxis by the development of vacc[illegible] techniques is now being investigated [illegible] techniques is now being investigated [illegible] clinical application of these techniques [illegible] justified [1]

Summary

A male patient aged 31 years, with a cytome[illegible] lovirus (CMV) myocarditis is described [illegible]

ormal limits (Fig 4) Also the echocardiogram showed no athologic findings The ESR normalized to 7 mm There ave been several reexaminations of the patient to the date of porting none of which have shown signs of recurrence

iscussion

The diagnosis of cytomegalovirus infection has een improved in recent years because of the evelopment of laboratory methods for determi ation of different cytomegalovirus immunglobu ns (IgG IgM IgA) by immunfluorescence[49 5] herefore the diagnosis of a fresh infection is not pendent on the laborious virus isolation [2] he presence of virus specific IgM antibodies pecially seems to be very helpful for diagnosis of cent CMV infection In our case reported here e were able to detect

1 a cytomegalovirus IgM antibody titer of > 64

2 a fourfold increase in the titer of comple ent fixing antibodies and

3 virus isolated from urine

hus a recent CMV infection is supported by veral diagnostic parameters

In the older child and in the adult the appear nce of IgM antibodies is a reliable sign of an tive process[20 1] even if relatively low KBR ters of 1 16 are found[3] Usually the IgM anti odies will also be eliminated from the serum veral months after the infection[5] and therefore ill have a great diagnostic significance

The IgG antibodies however may be demon rable for years[23] and therefore serve as a sign of past infection In the isolation of the virus from rine care must be taken to avoid rapid inactiva on of the virus at room temperature and there re the specimen must be quickly transported to e virology laboratory

Cytomegalovirus infection is frequently asso ated with other severe conditions such as leu emia malignant lymphoma lymphogranuloma yocardial infarction pneumonia fungus infec on liver abscess toxoplasmosis sepsis miliary iberculosis or other debilitating condi ons[8 8 45 58] or appears after cytostatic mmunsuppressive and corticosteroid drugs ransplantation of the kidney blood transfusion open heart surgery[1 1 19 9 4 7 58] should be emphasized that it also may occur in eviously healthy and unmedicated per ns[10 2 2 1 2 3 55 57]

The slightly elevated ST segments resemble the ectrocardiographic changes seen in pericarditis combined with myocarditis This interpretation is not supported by the clinical findings as our patient did not experience pericardial pain and a pericardial friction rub was never elicited

Fig 2 Chest x ray on admission showing cardiomegaly and pulmonary congestion.

The prognosis of cytomegalovirus myocarditis is not universally agreed upon Thus Sterner and colleagues[5] in two of 17 patients aged between 6 and 71 years with serologic and virologic evidence of cytomegalovirus infection and Klemola and co workers in a female patient aged 18 years and in a second female patient aged 66 years and also in a male patient aged 19 years with serolog ically verified cytomegalovirus mononucleosis saw transient flattening and inversion of T waves in the electrocardiogram Our patient with signs of heart failure distinct alterations in the electro cardiogram and cardiomegaly on x ray recov ered completely only after prolonged bedrest

In the patient of Wilson Morris and Rees there was a partial remission At the time of writing their paper the patient had survived with cardiac residuals such as alterations in electro cardiogram and cardiomegaly on x ray The 14 year old boy described by Tiula and Leinikki[7] died with signs of cardiogenic shock The main clinical manifestations were carditis hepatitis and consumption coagulopathy Myocardial in sufficiency developed and worsened in spite of digitalis treatment There was a seroconversion in

nowed a high IgM antibody titer for cytomegalovirus infection of 1 1 024 and a rise of the titer or complement fixing antibody from 1 < 16 to 256 CMV could be isolated from the urine investigations for other etiological factors were negative and we assumed a connection between the cytomegalovirus infection and the myocardial involvement

We would like to thank Mr G Morrice M D Linkton Memorial Hospital Newark Ohio 430.. U S A for his assistance in the preparation of this paper

Chamber	*Pressure*	*Oxygen saturation*
Right atrium	a = 12	
	v = 12 (10)	
Right ventricle	12/7 5 10	
Pulmonary artery	12/7 (10)	52%
Left ventricle	85/0 7	
Aorta	85/65 (72)	100%

Pressure tracing identical (see Fig 3)

Neck veins were not prominent There was no appreciable precordial impulse The heart sounds were muffled in intensity and there were no murmurs or gallop sounds Lungs were clear to auscultation A chest roentgenogram (Fig 1) showed considerable cardiomegaly the cardiac silhouette occupying almost the whole of the hemithorax Pulmonary vascular markings were unremarkable The electrocardiogram (Fig 2) revealed normal P waves a QRS frontal plane axis of +120 degrees, generalized low voltage complexes with non specific ST T changes a precordial tracing showed qr complex of very low amplitude in Lead V and very tiny complexes from Leads V to V Cardiac catheterization revealed the characteristic finding of identical right atrial right ventricular and pulmonary artery pressure tracings (Fig 3) A simultaneous electrode catheter intracardiac tracing for diagnosis of Ebstein s disease was of no help since pressure tracings of the right atrium and right ventricle were similar The left heart study revealed normal pressures (Table I) A right atrial cineangiogram showed a normally located tricuspid valve enormous dilation of the right ventricle which formed most of the cardiac contour with very scanty trabeculae (Fig 4) Pulmonary artery filling was delayed and clearance of the dye from the right ventricl was very slow a left ventricular cineangiogram was normal

These hemodynamic and angi graphic features suggested the diagnosis of parchment right ventri le with normal tricuspid valve (Uhl s anomaly) In view of persistent refractory right heart failure and the failure to thrive the child was subjected to superior vena cava right pulmonary artery anastomosis (Glenn s operation) At surgery the right atrium was found to be hypertrophied and enlarged. The right ventricle was tremendously enlarged and very thin The child was well for 3 hours after operation when sinus bradycardia to 25/minute with intermittent juntional escape beats was noted This was accompanied by profound hypotension. Parenteral atropine was of no help Transvenous right ventricular pacing was tried from different sites but capture could not be obtained and before left ventricular epicardial pacing could be tried the child died

Postmortem examination The autopsy was limited to heart and lungs The lungs showed chronic passive hyperemia and small peripheral pulmonary emboli.

Gross examination (Fig 5) The heart was enlarged. The combined weight of heart and both lungs was 250 g The right atrium was hypertrophied and enlarged The endocardial surface showed a postmortem thrombus on the right free wall There was a patent shunt between the superior vena cava and the right pulmonary artery with a purse-string suture at the junction of the right atrium and superior vena cava The tricuspid orifice was dilated but the cusps and subvalvular apparatus were normal The right ventricle was enormously enlarged with areas of sacculation The myocardium could not be recognized in the anterior surface and outflow tract of the right ventricle Scanty myocardium with trabecular pattern could be identified in portions of the inflow tract of the right ventricle and the thickness of the wall in these areas varied from less than 1 mm to 3 mm The endocardium was considerably thickened and appeared whitened in the inflow and outflow tract The pulmonary orifice diameter was normal but at the site of the pulmonary valve there were rudimentary cusps could be identified These were very thin and delicate The pulmonary trunk and branches were normal

The left atrium left ventricle mitral and aortic valves were normal The coronary arteries and its branches were normal

s anomaly is a rare condition characterized y partial or complete absence of the myocar um of the right ventricle and its replacement by broelastic and adipose tissue in the presence of a ormal tricuspid valve[1-13] Although the orig al description was in a heart with normal ulmonic valve pulmonary atresia pulmonary enosis and atrial septal defect have been ported in association with Uhl s anomaly

he antemortem diagnosis of this condition is ry rare and only three cases have been de ribed.[3 11] The present report is the fourth ase of Uhl s anomaly diagnosed by characteristic emodynamic and angiocardiographic features he patient died in the immediate postoperative eriod following Glenn s operation Autopsy vealed partial parchment right ventricle ormal tricuspid valve and rudimentary pulmo ary valve This association has not been ported previously

ase report

V K., a 4-year-old male child, was the product of a full term ormal delivery (birth weight, 2.5 kg) When the infant was 6 onths old his mother noticed swelling of the body besides his ilure to grow well. The child was admitted to one of the city ospitals where examination revealed facial puffiness, pitting dema, muffled heart sounds, and no cardiac murmur The ver was enlarged 5 cm. below the right costal margin. In view radiological evidence of gross cardiomegaly with clear lung lds, a pericardial tap was done but no fluid could be

Fig 1 Roentgenogram of the chest of a 4 year-old male patient with Uhl s anomaly showing enormous cardiomegaly and clear lung fields.

aspirated. The child was started on digitalis and diuretics, the edema subsided and hepatomegaly regressed, but there was no change in the cardiac size Despite regular treatment, the congestive heart failure continued to progress for 3 ½ years and the child was admitted to G.B Pant Hospital, New Delhi, in August 1977 Milestones of the child were delayed. There was no history of dyspnea cyanosis, anoxic spells, or repeated chest infections.

Physical examination revealed an ill looking child (height 96 cm., weight 10 kg.) with generalized edema. There was no central cyanosis or clubbing of the digits. Peripheral pulses were regular but of low volume Blood pressure was 90/70 mm Hg. The liver edge was 6 cm below the right costal margin

ig 5 Autopsy specimen of the heart with the right ventricle opened up showing the trabecular pattern in the right ventricular inflow tract and the parchment like body and outflow Note the rudimentary pulmonary valve leaflets *(arrow)*

graphic findings in this condition are similar pulse contours in the right atrium right ventricle and pulmonary artery elevated right ventricular end diastolic pressure and pulmonary artery diastolic pressure due to a prominent a wave[3] The right ventricle thus functions as a reservoir for venous blood Differentiation from Ebstein s disease is possible on angiocardiography which reveals a normally located tricuspid valve in Uhl s disease with enormous right ventricular dilatation and with absent or scanty trabeculae Pulmonary artery filling is delayed Scanty delayed filling of the left heart can be seen in the levophase of the right sided angiocardiogram[3, 1] The echocardiographic findings of diastolic pulmonary valve opening increased right ventricular dimensions delayed tricuspid closure and abnormality of the mitral valve have been reported in an isolated case report The absence of a diastolic pulmonary regurgitation murmur and the normal size of the main pulmonary artery and its branches signifies that there was no appreciable pulmonary regurgitation in the present case despite rudimentary pulmonary valve leaflets

The prognosis is these cases is very poor Gasul and colleagues have suggested superior vana cava right pulmonary artery anastamosis as a surgical remedy for this condition and have reported a case with a successful outcome

The postoperative rhythm disturbance seen in our patient seems to have arisen due to surg[illegible] trauma or edema in the region of the sin[illegible] node by the purse string suture The failure of right ventricular endocardial pacing which we encountered has also been recently experienced by Bharati and associates[1] in a case of Uhl[illegible] anomaly which presented with a complete h[illegible] block and narrow QRS complexes of recent o[illegible] The conduction system examination in the[illegible] revealed total destruction of both b[illegible] branches

ne myocardium showed an increase in the elastic tissue The muscle fibers showed edema vacuolization and nuclear hypertrophy

RIGHT VENTRICLE Microsections from the anterior surface and outflow tract showed complete absence of muscle with only adipose and fibrous tissue between the endocardium and epicardium In areas of inflow where scanty muscle fibers were present, the muscle fibres showed vacuolization and degenerative changes in the cytoplasm The nuclei were bizarre in shape and there were no inflammatory cells.

PULMONARY VALVE. The pulmonary valve cusps were represented by small vestiges of fibrous tissue with only occasional areas showing endothelial lining

The left atrium, left ventricle aortic valve mitral valve aorta and pulmonary trunk were normal

Discussion

Uhl's disease is a condition with partial or complete absence of the myocardium in the right ventricle and its replacement by fibroelastic and adipose tissue in the presence of a normal tricuspid valve[1, 13] In the literature others have included parchment right ventricle with atrial septal defect pulmonic stenosis and pulmonary atresia[14] The association of Uhl's anomoly with rudimentary or absent pulmonary valve has not been reported so far The differential diagnosis of Uhl's anomaly includes conditions like Ebstein's anomaly pericardial effusion primary endocardial fiberoelastosis glycogen storage disease of the heart and anomalous origin of the left coronary artery from the pulmonary artery

The patients with this disorder present in infancy with congestive heart failure without dyspnea unless there is an associated left-sided involvement like endocardial fibroelastosis Occasionally Uhl's disease has been reported as an incidental autopsy finding

Radiological examination shows a considerable cardiomegaly even occupying the whole of the left hemithorax[2, 3] The electrocardiogram shows generalized low voltage QRS complexes with or without evidence of P pulmonale[2, 11] The great majority of cases reported in the literature were diagnosed at autopsy[11] Most of the cases described were erroneously diagnosed as Ebstein's anomaly One of the cases reported in the literature was erroneously diagnosed as mediastinal tumor necropsy established the correct diagnosis This anomaly has been diagnosed antemortem only on three previous occasions[2, 10, 5] The typical hemodynamic and angio-

Partial intra atrial block seems to be a frequent electrocardiographic finding[1] Conversely dissimilar atrial rhythms due to a higher degree of intra or inter atrial block have been reported infrequently after the first clinical description[5] However since the electrical activity of one atrium or of a segment of the atria may not be registered by the conventional electrocardiogram (ECG) it seems reasonable to assume that the true incidence of these arrhythmias may have been underestimated

Recently several forms of dissimilar atrial rhythms were only detected by multiple intracardiac electrocardiographic tracings[5 11] These forms include electrical atrial standstill with flutter or tachycardia in another segment of the atria Persistent standstill of only one atrium in the absence of other heart disease has also been described[1]

We report here an unusual case of A V block and atrial fibrillation in the surface ECG in which the electrophysiological study demonstrated three areas in the right atrium each of them with different electrophysiological properties.

Case report

Clinical features A 54-year-old man followed up in the Outpatient Department because of complete A V block was referred to our laboratory for intracardiac stud[y] preceding 6 months he only complained of dizzi[ness] was no past history suggestive of heart disease a[nd] were administered. On examination he exhibited a rate of 40/minute Neither "a" waves nor can[non] were seen on the jugular veins. The blood pressure mm. Hg. A chest x ray film revealed slight cardiom[egaly] ECG showed atrial fibrillation, complete A V narrow QRS complexes, and a pattern of inco[mplete] bundle branch block. The "f" waves reflected very and could be seen only in some leads (Fig. 1A).

Electrophysiologic study After obtaining conse[nt] catheter was percutaneously introduced thro[ugh] femoral vein, and was placed across the septal le[aflet] tricuspid valve for bundle of His recordings, an[d] moved to various sites in the right atrium. Ano[ther] catheter was introduced through an antecubi[tal] pacing or recording electrograms from various right atrium, from the coronary sinus, and fro[m] ventricle An additional bipolar catheter was plac[ed] ent intraesophageal levels for recording left atr[ial] Filtered (40 to 400 Hz) intracavitary right heart e[lectrograms] were recorded simultaneously with surface leads tronics for Medicine DR 8 photographic record[er] speeds of 100 and 200 mm./sec. Electrical stimuli old, 2 msec. duration) were introduced by a Hewl[ett] Model 7804 A pacemaker

Results No atrial electrical activity could be with the catheter positioned near the sinus node 1B) and at different levels of the anterolateral right atrium. Catheter 2, placed at the highest po[rtion] interatrial septum, registered coarse fibrilloflutter interatrial septum, registered coarse fibrilloflutter is, waves of coarse atrial fibrillation (RA of Fig 1B catheter 2 was located at the lower portion of the septum and RA_1 showed the same features as However catheter 1 now placed at the coronary registered an irregular atrial activity (A waves) a 50/minute (RA) In other recording (Fig. 3), ca[theter] positioned at the atrial zone adjacent to the tr[icuspid] and fibrilloflutter waves were registered. Catheter located between both areas in which fibrilloflu[tter] ular atrial activity were obtained. The ... this tracing (RA) showed irregular waves of ver[y] tude with a rate of 450/minute These la[tter] coincide with the major deflections of RA Exc[ept]

Vertical time lines are 1 sec. apart See text for details.

lation (S) with 10 to 15 mA. performed in the atrial standstill zone was not propagated, as can be seen in Fig 4*A* Catheter 1 (RA) was located 1.5 to 2 cm away from the pacing catheter (S) In Fig 4*B* the latter was positioned in the right ventricle Ventricular endocardial stimulation (S) was not conducted to the coronary sinus area registered with catheter 1 (RA) The left atrial electrograms obtained by intracoronary sinus and intraesophageal catheters reflected fibrilloflutter waves (not shown)

The electrophysiological study was repeated two weeks later and the results previously described were confirmed

In the follow up period up to 7 months the surface ECG showed similar findings, and in spite of the fact that the patient remained asymptomatic a permanent pacemaker was indicated

Discussion

The diagnostic criteria and differential diagnosis of most forms of dissimilar atrial rhythms have been well summarized by Chung As can be deduced from the analysis of these data the scalar ECG gave sufficient information about the atrial events when the sinus rhythm coexisted with other dissociated regular atrial rhythms or when flutter or fibrillation in a segment of the atria developed during sinus rhythm Conversely in the other reported forms the diagnosis was only suspected or misinterpreted

According to Wu and colleagues[8] the electrocardiographic manifestations of an atrial rhythm are dependent upon (1) the atrial mass depolarized and (2) the vicinity of the recording electrodes to this atrial mass Thus in most instances only with multiple intracavitary electrograms is it possible to demonstrate atrial events in patients with unclear forms of atrial arrhythmias

In our patient the surface ECG showed complete A V block without detectable atrial activity in most leads Only in amplified rhythm strips could a slight irregularity of the baseline be seen and the diagnosis of atrial fibrillation was established However the possibility of an atrial standstill was considered The intracardiac study demonstrated three areas in the right atrium each of them with different electrophysiological properties Zone A persistent atrial standstill in the

demonstrate atrial events in patients with atrial arrhythmias They may be of important clinical significance given the large number of new antiarrhythmic drugs with very different electrophysiological effects recently introduced On the other hand the clinical features of this and other recently reported cases[3, 4, 11] demonstrate that dissimilar atrial rhythms may be registered in several types of heart disease In contrast earlier clinical studies suggested that atrial dissociation was almost always found in critically ill patients with intractable heart failure

Summary

A patient with complete A V block and atrial fibrillation was analyzed by multiple intra atrial electrograms Three areas were recorded in the right atrium each of them with different electrophysiological properties (1) persistent atrial standstill (2) irregular atrial activity with a rate of 50/minute and (3) fibrilloflutter waves with a rate of 450/minute The latter were also registered in the left atrium

This case illustrates another form of dissimilar atrial rhythms and provides additional evidence of the importance of recording multiple electrograms from each atrium in the evaluation of the atrial events in atypical atrial arrhythmias

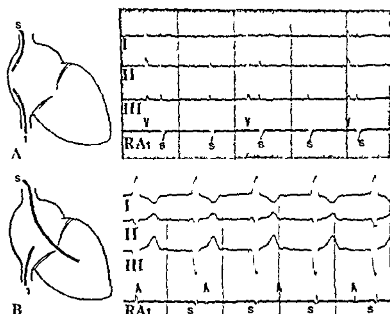

Fig 4 A Electrical stimulation performed in the atrial standstill zone (S) is not propagated (RA) Catheter 1 is located 1.5 cm away from the pacing catheter (S) B Ventricular endocardial stimulation is not conducted to the coronary sinus area recorded with catheter 1 (RA) See text

another independent atrial activity localized to a small area in the right atrium cannot be excluded In the left atrium fibrilloflutter waves were also registered His bundle electrograms were not identified in the two electrophysiological studies It is possible that the fibrilloflutter waves which were coarser in the vicinity of the tricuspid area than in the upper portion of the interatrial septum (Fig 3) masked the His potentials

Although the electrophysiological mechanism of atrial dissociation and other forms of dissimilar atrial rhythms have not yet been fully elucidated the above mentioned studies with intra atrial recordings provide evidence supporting the existence of inter and intra atrial blocks If an interatrial block is only partial a first degree of interatrial block occurs with two components (right and left) of the P waves separated by an isoelectric period as in Case 1 of Wu and colleagues[4] and in other reported cases with surface ECGs[1] If a higher interatrial block is present only some of the unilateral atrial depolarizations (right or left) are conducted to the other chamber and a second degree of interatrial block with or without Wenckebach phenomenon can be considered as in the cases reported by Zipes and DeJoseph[6] Finally if the interatrial block is complete a true atrial dissociation with two independent rhythms occurs Experimental and clinical studies suggest Bachman s bundle as the site of the block However in most cases of these so called third-degree of interatrial block the site of block appears to be located within the same atrium rather than between the two atrial chambers as in Case 2 reported by Wu and associates

In our patient the three dissimilar atrial rhythms were located in the right atrium The limits of the three different areas were well demarcated as could be demonstrated by multiple and repeated positioning of the catheters during the two electrophysiological studies performed These findings may be considered as evidence of the existence of two ectopic foci with complete exit and entrance blocks Furthermore the presence of a considerable area with atrial standstill presumably indicates an advanced degree of atrial disease This suggests that atrial fibers may show nonhomogeneous refractoriness with multiple sites of partial or complete intra atrial blocks However on the same basis it is also possible to assume the alternative explanation postulated by Zipes and DeJoseph[6] the slow atrial activity recorded in Zone B may be secondary to a constant filtering of the fibrillatory stimulus originating in Zone C and in the left atrium

The results of this study as well as previous publications emphasize the importance of recording multiple electrograms from each atrium to

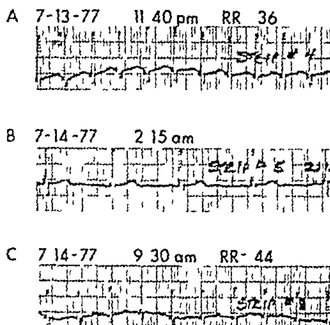

Fig 1 Holter monitor recording Patient No 1 *Panel A* was recorded during sleep and shows supraventricular tachycardia with a rate of 166 minute *Panel B* was also recorded during sleep and shows sinus rhythm *Panel C* was recorded in the early morning and shows supraventricular tachycardia at a rate of 136 minute The patient was resting quietly at the time Panel C was recorded and experienced no symptoms

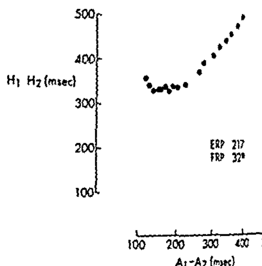

and retrograde direction was assessed by fixed rate pacing and the extrastimulus technique (Fig 2) using stimulation sites in the right atrium, coronary sinus (left atrium) and right ventricle The AV conduction system was normal and no tachycardia was induced during the study

Electroencephalographic findings The background rhythm of the EEG consisted of a well-developed and well modulated alpha rhythm at a frequency of 9 Hz The major abnormality detected was repetitive epileptiform discharges consisting of both sharp and spike wave transients arising from the lateral aspect of the right mid and anterior temporal regions These findings would provide the basis for a diagnosis of epilepsy of temporal lobe origin in symptomatic patients No cardiac arrhythmias occurred during simultaneous monitoring of the EEG and electrocardiogram

Clinical course The patient was treated initially with phenytoin 100 mg three times daily but symptoms persisted He then was treated with carbamazepine 400 mg twice a day On this dose a carbamazepine level (drawn 12 hours after the preceding dose) was 4 mcg ml After one month of therapy neurologic symptoms and all symptomatic arrhythmias had resolved A 24 hour Holter monitor recording showed only sinus rhythm

Clinical history

Spontaneous paroxysmal supraventricular tachycardia (PSVT) can almost always be reproduced in patients with this arrhythmia by programmed stimulation in the electrophysiology laboratory [3] The arrhythmia may be caused by reentry within the atrioventricular (AV) node reentry within the sinus node or reentry using an accessory A V pathway [3] We recently studied two patients who had multiple arrhythmias including PSVT Electrophysiologic mechanisms for the arrhythmias could not be demonstrated by programmed stimulation in either patient Both patients were found to have epileptiform abnormalities demonstrated by electroencephalogram (EEG) A primary neurologic abnormality was the probable cause for the arrhythmias in these patients

Case reports

Patient No 1

Clin cal history Patient No 1 was a 21 year old college student when he was referred to Duke University in April 1978 for treatment of cardiac arrhythmias His first recollection of symptoms suggestive of tachycardia occurred in October 1976 At that time he was bowling and experienced dizziness and dyspnea A nurse was present and stated that his pulse was very fast " The episode terminated abruptly after 30 minutes Two weeks later he experienced palpitations dyspnea, and nausea in a restaurant Observers reported that he lost consciousness for approximately 10 minutes but was not incontinent and did not have tonic or clonic seizures He awoke and returned home where his mother felt his pulse and noted that it was approximately 200 beats/minute He continued to have two or three attacks of altered consciousness per month between October 19"6 and July 19 7 Some attacks were accompanied by palpitations other similar episodes were not In July 1977 a Holter monitor recording demonstrated two episodes of supraventricular tachycardia (Fig. 1) that caused no symptoms During tachycardia the QRS morphology was normal. He was treated with digoxin, propranolol quinidine and combinations of these drugs but none modified the frequency or severity of tachycardia or dizziness. He was referred for further evaluation and treatment

The vital signs were normal and the cardiovascular and neurologic systems were normal by clinical examination An electrocardiogram recorded at the time of admission was normal

The patient had four hospital admissions between April and August 19"8 During these hospitalizations he had continuous monitoring of his electrocardiogram in the Coronary Care Unit Holter monitor recordings were also made The dominant arrhythmia was sinus arrest with an ectopic atrial pacemaker at a rate slower than the sinus rate The patient had no symptoms and no spontaneous tachycardias while in the hospital

Results of electrophysiologic testing Basic A V conduction intervals are shown in Table I Sinus node recovery times were normal. The A V conduction system in the antegrade

Table I Conduction intervals

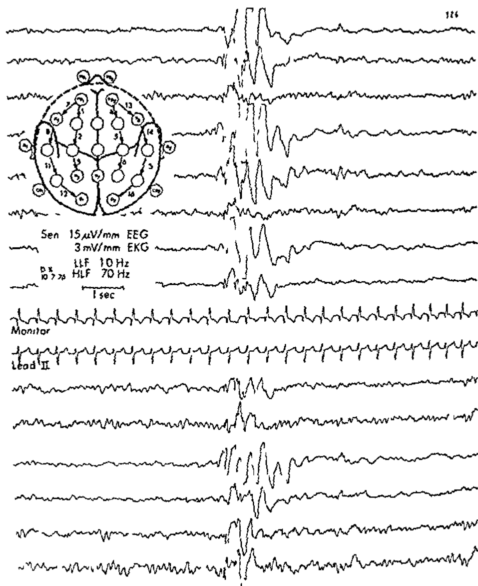

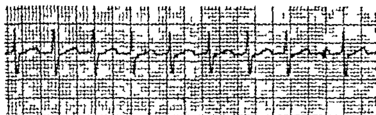

Fig 4 Epileptiform discharges on EEG on Patient No 2 Supraventricular tachycardia is present throughout the tracing

one case to drive a car) even though tachycardia persisted

Paroxysmal supraventricular tachycardia was a prominent arrhythmia recorded in both patients but three features of the arrhythmia were unusual As noted above PSVT rarely causes loss of consciousness Also common antiarrhythmic drugs failed to alter the frequency duration or severity of attacks In addition no etiology could be found for the PSVT and other arrhythmias when electrophysiologic studies were done This arrhythmia has been studied intensively with electrophysiologic techniques for several years The etiology can be demonstrated by laboratory methods in approximately 90% of patients in whom PSVT occ… spontaneously [13]

Both the presence of neurologic sympt… without arrhythmias and the unusual feat… the PSVT led us to consider alternate expl… tions in these patients referred for cardiac e… ations A primary neurologic abnormality ca… seizures and subsequent initiation of arrhyt… was an hypothesis that would explain all … findings Epileptiform discharges on the … EEG of both patients supported this … hypothesis

A correlation between the EEG abnorm… and the cardiac arrhythmias would p… important evidence implicating the epilep…

Fig 3 Paroxysmal supraventricular tachycardia Patient No 2 This tachycardia had been present for over 12 hours when its termination was recorded on this monitor lead The last QRS was the result of a sinus beat

described at the time of the second attack. Phenobarbital 30 mg. orally twice daily was added to digoxin and propranolol 10 mg orally twice a day was begun in 1975 He continued to have dizzy spells, bradycardia and tachycardia He lost consciousness again in December 1975 was taken to a hospital emergency room and was found to have a rapid supraventricular tachycardia Phenobarbital was increased to 30 mg three times daily and propranolol was increased to 20 mg also three times a day Quinidine 200 mg four times daily was begun in February 1976 and digoxin and phenobarbital were continued. In September 1976 he again lost consciousness His heart rate recorded by the school nurse was 180 beats/minute He was admitted to a hospital and PSVT converting to sinus rhythm was recorded on a monitor lead (Fig 3) He was referred for further evaluation and treatment

The vital signs were normal and the cardiovascular and neurologic systems were normal by clinical examination An electrocardiogram recorded at the time of admission was normal.

During the course of hospitalization the patient was observed with continuous ECG monitoring in the Coronary Care Unit A variety of arrhythmias were documented including sinus tachycardia (rate 210 beats/minute) sinus arrest (2 6 second pauses) junctional rhythm with retrograde block junctional rhythm with retrograde conduction multifocal ventricular tachycardia, first-degree atrioventricular (A V) block, Mobitz Type I second-degree A V block and high grade A V block During periods of sinus rhythm there were frequent episodes of sinus arrest followed by appearance of an ectopic atrial pacemaker at a rate slower than the sinus rate (similar to the rhythm recorded in Patient No 1) No symptoms occurred during arrhythmias

Results of electrophysiologic testing Basic conduction intervals (Table I) and sinus node recovery times were normal Using stimulation sites in the right atrium and right ventricle electrophysiologic tests were performed The A V conduction system was tested with fixed rate pacing and the extrastimulus technique The A V conduction system was normal and no tachycardia was initiated

Electroencephalogram findings The background rhythms of the EEG consisted of a well developed alpha rhythm at a frequency of 9 Hz The principal abnormalities consisted of (1) irregular intermittent theta and delta transients in the left temporal regions throughout the waking record and (2) bilaterally synchronous 3 to 4 per second spike and wave discharges maximal in amplitude in the frontal and central regions (Fig 4) Despite the focal theta and delta transients in the left temporal region no focal (as opposed to bilaterally synchronous) cortical spiking was detected The focal slowing suggested the presence of a structural lesion in the left temporal region. The synchronous spike wave discharges would be consistent with a diagnosis of cortical reticular epilepsy in a symptomatic patient Supraventricular tachycardia was detected by simultaneous monitoring of the electrocardiogram during the EEG However the supraventricular tachycardia did not reflect a consistent temporal relation to occurrence of EEG abnormalities

Clinical course A ventricular demand pacemaker was implanted in October 1976 He began taking phenytoin 100 mg three times a day He continued to have supraventricular tachycardia Treatment with digoxin 0.25 mg three times daily was begun Supraventricular arrhythmias persisted and digoxin was discontinued and propranolol and a combination of propranolol and disopyramide were tried. No combination of drugs prevented tachycardia but the patient did not have another episode of loss of consciousness The patient was found dead in a swimming pool in April, 1978 At the time of death, the pacemaker was functioning normally The brain was normal at autopsy

Discussion

The ages of these patients and several other factors strongly suggest that the arrhythmias in these two patients did not cause the neurologic symptoms Paroxysmal supraventricular tachycardia is not usually associated with syncope in children and one patient had episodes of dizziness and disorientation which were not accompanied by palpitations Also during episodes of loss of consciousness accompanied by tachycardia the tachycardia persisted after consciousness returned Neurologic symptoms secondary to an arrhythmia usually last as long as the arrhythmia does or until the victim has fallen to a recumbent position When consciousness returned our patients were able to resume normal activities (in

discharges as a cause for the cardiac arrhythmias Despite the occurrence of the cardiac arrhythmia during EEG monitoring in Patient No 2 such a correlation was not established This finding is not surprising in light of two facts First even when abnormally excitable neural tissue lies in immediate proximity to the scalp (e g *epilepsia partialis continuans* arising from precentral gyrus) a close correlation between epileptiform discharges on EEG and the clinical seizure can be established in less than 50% of cases Second accurate sampling of epileptiform activity in depths of the brain by sampling scalp EEG is exceedingly difficult Since the brain regions implicated by stimulation studies as causing arrhythmias are remote from the scalp (e g diencephalon and orbital frontal cortex) [1] difficulties in establishing a close correlation would be expected Thus the failure to establish a one to one relationship between the PSVT and the scalp EEG abnormalities in no way excludes seizures as a cause of the arrhythmias

Walsh and colleagues[1] described a patient in whom a supraventricular arrhythmia occurred immediately following the onset of epileptiform discharges on the EEG Unfortunately electrophysiologic testing of that patient was not done and the absence of an intrinsic cardiac abnormality can not be assumed

Abolition of both the arrhythmia and the neurologic symptoms in Patient No 1 by a single antiepileptic agent carbamazepine is consistent with the primary neurologic cause of a cardiac arrhythmia postulated Carbamazepine has some antiarrhythmic effects on ventricular tachycardia induced by digitalis or coronary artery ligation in dogs[1] It is however also related to the tricyclic antidepressants that have arrhythmogenic potential in man The effect of carbamazepine on arrhythmias in humans is not known

The findings in our two patients in which arrhythmias appeared to be secondary to partial seizures strengthen the argument that some arrhythmias have a nerual origin Arrhythmias have been induced by stimulation of the diencephalon of experimental animals and bradycardia[1] and tachycardia have been reported in humans with epilepsy Recent investigation of the neural influence on arrhythmias has identified an important role for psychologic stress Potentially lethal arrhythmias have been linked to psychologic stress in two patients who had no known cardiac abnormalities [19] Future study of the origin of arrhythmias may include studies of the neurologic system

Summary

This report describes a clinical syndrome of arrhythmias that may have neural origin Two patients presented with episodes of loss of consciousness disorientation and paroxysmal supraventricular tachycardia (PSVT) One patient reported experiencing neurologic symptoms without tachycardia When electrophysiologic testing with intracardiac recordings and programmed stimulation yielded no abnormalities that could account for the arrhythmias a primary neurologic abnormality was sought The electroencephalograms of both patients showed epileptiform discharges that supported this hypothesis Arrhythmias and neurologic symptoms were controlled by treatment with the antiepileptic drug carbamazepine in one patient Findings in these two patients suggest that in some patients arrhythmias may be a manifestation of seizures

Including fungi. (From Wilson W R and Washington J A II Infective endocarditis—a changing spectrum? (Editorial) Mayo Clin Proc 52 2.4 1977 Reproduced by permission.)

1970s however the average number of cases of IE increased from 24 5 per year 20 years ago to 44 per year during the 1970s and the number of patients with viridans streptococcal infections increased from [illegible] per year It is clear that there are [illegible] patients with viridans streptococcal IE [illegible] more patients with IE caused by [illegible] microorganisms Part of this changing spectrum [illegible] the result of nosocomially acquired infection associated with the increased use of intravascular prostheses life support mechanism monitoring systems and invasive diagnostic techniques Another factor in the changing microbiologic spectrum of IE is the apparent increase in the number of patients with IE associated with intravenous drug abuse Nosocomially acquired IE or IE associated with intravenous drug abuse is often due to gram negative bacilli *Candida* and opportunistic microorganisms—uncommon causes of IE in the 1950s

Despite the changing spectrum of IE at least 75% of infections are caused by streptococci or staphylococci The selection of antimicrobial agents for the therapy of infections caused by these microorganisms depends on the penicillin susceptibility of these isolates An understanding of the differences between streptococci and staphylococci that are susceptible to penicillin and those that are resistant to penicillin is essential for the selection of appropriate antimicrobial agents and frequently for determining the length of antimicrobial therapy

Role of blood cultures in diagnosis of IE

In patients with suspected IE the most imp[illegible] tant laboratory finding is the isolation of bacteri[illegible] or fungi from at least two or more blood cult[illegible] obtained at intervals during a 48 hour per[illegible] Bacteremias associated with IE are usu[illegible] continuous[6,7] and if any blood cultures are p[illegible] tive, most of the other cultures drawn will al[illegible] positive[8,9] Although bacteremia is prob[illegible] continuous Weiss and Ottenberg[1] found s[illegible] showers of larger numbers of bacteria tempor[illegible] related to an increase in patients body temper[illegible] tures Wright[11] was unable to document [illegible] temporal association with fever The ord[illegible] magnitude of bacteremia is usually relatively [illegible] In 83% of cases the quantitative blood cul[illegible] contained less than 100 colonies per mi[illegible] ter[7,9,10] Studies have shown that cultures [illegible] peripheral venous blood are as likely to be p[illegible] tive as those of arterial blood[7,8,1] Blood cul[illegible] should not be obtained through a preexis[illegible] intravenous catheter because pericatheter c[illegible] taminants or colonizers may be drawn up in [illegible] blood sample and contaminate the blood cul[illegible] medium[12]

Belli and Waisbren[11] reported that 5? of [illegible] cases of IE were diagnosed with the first bl[illegible] culture and in only six cases were more than [illegible] blood cultures necessary Werner and associ[illegible] in a similar study, found that streptococci [illegible] isolated in 96% of cases from the first b[illegible] culture and in 98% from one of the first two b[illegible] cultures Staphylococci were isolated from [illegible] first culture in 90% and from one of the fir[illegible] cultures in 100% of cases Antimicrobial the[illegible] given within 2 weeks before blood cultures [illegible] obtained reduced the positive cultures in [illegible] cases of streptococcal endocarditis from 9? to [illegible] ($P < 0.02$)[9] In cases of IE caused by microor[illegible] isms other than streptococci and staphylococ[illegible] the causative agent was isolated from 82% of c[illegible] in the first blood culture and from 100% in ca[illegible] the first two blood cultures[9]

In conclusion on the basis of the above d[illegible] patients who have not received prior antim[illegible] bial therapy, it is rarely necessary to ob[illegible] than three separate sets of blood cultures [illegible] 24 hour period on two consecutive days [illegible] patients suspected of having IE The t[illegible] collection of blood cultures just before an [illegible] pated increase in temperature may [illegible] increase the likelihood of a positive blood cu[illegible]

Infective endocarditis therapeutic considerations

Walter R Wilson M D
Donald R Nichols M D
Rodney L Thompson M D
Emilio R Giuliani M D
Joseph E Geraci M D
Rochester Minn

During the preantibiotic era recovery from serious bacterial infections was not uncommon That patients survived these infections is testimony to the major role played by host defense mechanisms in controlling or eradicating many types of bacterial infections This is not the case with infective endocarditis (IE) Host defense mechanisms play little role in the control of IE and before the discovery of antibiotics the mortality rate of patients with IE was virtually 100% In no other infection does cure seem to be so dependent upon the administration of appropriate bactericidal antimicrobials The pathophysiologic events that result in the formation of valvular vegetations composed of dense networks of avascular fibrin platelet matrices appear to protect microorganisms buried within from phagocytes and other host defense mechanisms

Effective antimicrobial therapy exists for most patients with IE The role of the microbiology laboratory in the selection of appropriate antimicrobial therapy is probably more important in the management of patients with IE than in that of any other infectious disease process The purpose of this paper is to discuss the microbiologic spectrum of IE the role of the microbiology laboratory and the rationale for the selection of antimicrobial therapeutic regimens and to consider general principles for the medical and surgical management of patients with IE

Microbiologic cause of IE

Virtually any microorganism is capable of causing IE[1] Table I lists the microbiologic causes of IE in 172 patients seen at the Mayo Clinic from 1951 through 1957 and compares these data with those from 219 patients with IE treated at the Mayo Clinic 20 years later The data presented in Table I suggest that the microbiologic causes of IE in the 1950 s differed from those of the 1970 s The increasing number of reports describing uncommon causes of IE is probably attributable to two factors (1) improved microbiologic techniques and (2) a changing microbiologic spectrum The impact of improved microbiologic techniques is apparent in patients with gram negative bacillary other infections and culture negative endocarditis Some gram negative bacilli such as *Haemophilus* species are slow growing microorganisms with special growth requirements These fastidious microorganisms constitute a major portion of the gram negative bacillary cases of IE in the later group of patients seen at the Mayo Clinic Of the 25 patients seen with IE in the 1970 s caused by other microorganisms six had infections with anerobic gram positive cocci In the 1950 s anerobic microbiology was largely a research tool and patients with IE due to anerobic bacteria would have been classified as culture negative Although improved techniques may explain some of the differences between IE of the 1950 s and that of the 1970 s the experience at the Mayo Clinic and elsewhere indicates that the bacterial spectrum of IE is changing The percentage of patients with viridans streptococcal IE seen at the Mayo Clinic declined from 53% in the 1950 s to 37%

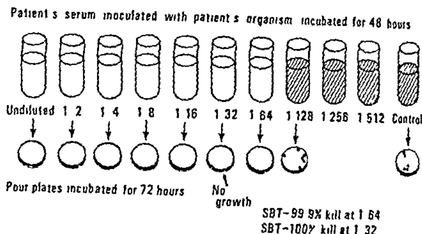

Fig 2 In vitro susceptibility testing serum bacterial test

cin) the serum sample should be obtained at the anticipated peak concentration of the agent administered intermittently A standard inoculum of the patient s bacteria is transferred to each tube and the tubes are incubated at 37° C for 48 hours Tubes showing no visible evidence of growth and the last tube showing growth are subcultured into pour plates as described above The results are expressed as the highest dilution of patient serum which kills 99 9 to 100% of the inoculum Although it is difficult to interpret accurately the results of the SBT considerable clinical experience suggests that antibiotic treatment should be adjusted to achieve a peak serum concentration of antimicrobials which results in an SBT of 1 8 or more

It is desirable to measure serum concentrations of antibiotics from the same specimen of serum used to determine SBT The serum concentrations assist in the interpretation of the SBT A low SBT may be related to a simultaneously low serum concentration of antimicrobial rather than to a lack of bactericidal effect and this suggests that the dosage should be increased Serum concentrations should also be measured periodically throughout the course of treatment to ensure adequate therapeutic levels in excess of the MBC and to avoid accumulation in the serum of potentially toxic concentrations of antimicrobials

Occasionally with unusual organisms or those resistant to multiple drugs or as a guide for determining optimal combinations of antimicrobials in vitro tests of synergism between antimicrobials may be desirable Methods for determining antimicrobial synergy have been described [23-25]

Treatment of IE—general considerations

4 In general antimicrobial therapy sho[...]

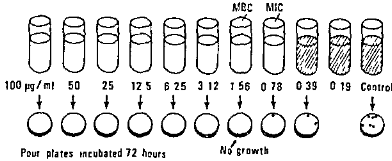

Fig 1 In vitro susceptibility testing minimum bacterial concentration

but the limitations of this recommendation are obvious An important exception to the reports that state that blood cultures are usually positive in patients with IE is that of patients with fungal IE Patients with IE caused by *Candida* species often have positive blood cultures however other causes of fungal IE notably *Aspergillus* species are usually associated with negative blood cultures Diagnosis may occasionally be established by staining and culturing emboli removed surgically from peripheral vessels [1] More often the diagnosis of fungal IE is made at the time of cardiac valve replacement or at autopsy

In vitro susceptibility testing

It is important to determine accurately the in vitro susceptibility of organisms causing IE The most widely used test and the simplest to perform is the minimum inhibitory concentration (MIC)—the lowest concentration of antibiotic which will inhibit the growth of the causative bacteria MIC may be measured by disk diffusion agar dilution or broth dilution methods

The minimum bactericidal concentration (MBC)—the lowest concentration of antimicrobial which will kill 99 9 to 100% of the inoculum—is also helpful in determining optimal therapy The broth dilution technique is used to determine MBC (Fig 1) Briefly described 10 serial twofold dilutions of the desired antibiotic are prepared in nutrient broth in sterile test tubes The concentration of antibiotic in the 10 tubes of nutrient broth decreases sequentially—100 µg/ml in tube 1 50 µg/ml in tube 2 25 µg/ml in tube 3 and so on to 0 19 µg/ml in tube 10 A standard inoculum of the patient s bacteria is then added to each tube After overnight incubation at 37° C the tubes are examined The lowest concentration of antibiotic which completely inhibits visible growth as indicated by lack of turbidity in the media is the MIC From each of the tubes that have no visible turbidity and from the first tube exhibiting the turbidity aliquots are removed and subcultured into media for pour plates After 48 and 72 hours of incubation the lowest concentration of antibiotic which kills 99 9% of the inoculum (less than 10 colonies per plate) or 100% of the inoculum is recorded as the MBC

The disk diffusion or agar-dilution MIC provides valuable information for the *initiation* of antimicrobial therapy However most clinicians experienced in the treatment of patients with IE believe that broth-dilution MIC and MBC are more accurate in indicating susceptibility The concentration of antimicrobial agents achieved in fibrin clot vegetations may be less than that measured in serum and dosages of antimicrobials should be adjusted so that ideally the peak serum concentration of antimicrobial exceeds the MBC

The serum bactericidal test (SBT) is a modification of the broth dilution test of antimicrobial susceptibility Instead of serial dilutions of an antimicrobial solution serial twofold dilutions are prepared of the patient s serum containing the antibiotic that has previously been administered to the patient (Fig 2) Serum samples should be obtained at the anticipated peak serum antimicrobial concentration usually 1 hour after administration of an antibiotic If the patient is receiving two antimicrobials one continuously and one intermittently (that is continous intravenous penicillin and intramuscular streptomy

tive therapy outlined below or presented in standard texts and references

Penicillin sensitive viridans and nonenterococcal group D streptococcal IE (MIC $\leqq$ 0 1 $\mu g/ml$)

Penicillin sensitive viridans and nonenterococcal group D streptococci are the most frequent causes of IE, constituting at least 45% of all cases [1 4] These organisms are part of the normal microbial flora of the oral cavity and gastrointestinal tract Species of viridans streptococci are especially common in the oral cavity where they form plaques on the surface of teeth At least one species *Streptococcus mutans* is important in the production of dental caries [27] It has been recognized for many years that dental manipulations may result in transient polymicrobial bacteremia, and a history of recent dental procedures often antedates the onset of symptoms of IE [3 28 31] Viridans streptococci are considered noninvasive saprophytes and why these rather placid organisms and not other more aggressive microbes found in the oral cavity, result in IE has been a subject of considerable interest Recent studies have demonstrated that viridans streptococci *S bovis* and some enterococci are considerably more adherent to the endothelium of heart valves than are other bacteria This increased adherence is probably due to the production of dextran which increases bacterial stickiness [33 35] Not coincidentally then viridans and nonenterococcal streptococcal IE is most often caused by dextran producing strains—*S sanguis S mutans S bovis*—and IE caused by non dextran producing strains—*S salivarius*—is rare [3 39]

Hunter originally suggested the use of combined penicillin streptomycin therapy for treatment of viridans streptococcal IE based on in vitro studies demonstrating synergy against isolates of viridans streptococci [4] That the combination of penicillin and streptomycin is superior to penicillin alone in the treatment of these infections is supported by data collected from studies of experimental animal IE Combined penicillin and streptomycin was more effective than penicillin alone in preventing experimental endocarditis and in the treatment of established infection In patients with IE caused by viridans streptococci who were treated with dihydrostreptomycin and low dose penicillin therapy [46] early studies reported relapse rates of 6 to 11%

Table II lists three generally accepted meth and alternatives for the antimicrobial thera penicillin sensitive viridans and nonenteroco group D streptococcal IE Recently reported [1 49] a prospective study of 68 patie with streptococcal IE (54 patients with vi and 14 with *S bovis* infections) who were tre with short term combined intramuscular thera with procaine penicillin and streptomyc i none of these patients did the infection re and the mortality rate was 3% Earlier o e (J E G) reported only one relapse amon surviving patients treated for 2 weeks with va ing dosages of intramuscular penicillin and str tomycin [49 51] Together with our 68 patients th additional 66 patients constitute a total of 1 patients who were treated similarly with o one relapse (0 7%) Some authors suggest patients whose symptoms have been pres f more than 3 months may be at higher ri relapse and that treatment should be conti with penicillin G alone for an additional 2 weeks However 14 of our 68 patients (21%) who w treated with short term therapy had sym for more than 3 months and in none was th relapse Moreover two of our 68 patients ha a relapse elsewhere after 4 weeks of intrave penicillin G therapy alone and both pati were cured with short term combined therap

Some viridans streptococci are relatively re tant to penicillin (MIC > 0 1 $\mu g/ml$ MBC $\geqq$ 3 12 $\mu g/ml$) Some investigators that patients with infections caused by th relatively penicillin resistant microorga should receive antimicrobial therapy identic that for enterococcal endocarditis (see b and Table III) In our study 37% of isolate relatively penicillin resistant according to criteria [31] All of these patients were cur infection with 2 weeks of intramuscular com penicillin streptomycin therapy

Wolfe and Johnson [3] found no relapses i retrospective study of 35 patients with IE c by penicillin sensitive viridans streptococ were treated with a mean daily dose of 1 million units of penicillin for 30 4 days and 1 of streptomycin for 13 4 days In unpu data these authors cite in excess of 60 add patients treated similarly without relapse T sett and Hurst [1] reported no relapses in 60 patients in whom a similar therapeutic men had been used

Streptomycin associated vestibular t

. red parenterally rather than orally ... otion from the gastrointestinal tract of orally administered antimicrobial agents may be unpredictable

5 Patients who are receiving treatment for IE should be examined daily throughout their hospital course Subtle changes in body weight blood pressure cardiac auscultatory findings jugular venous distention and so on may presage abrupt hemodynamic decompensation Clinicians should also be alert for the occurrence of large arterial ... especially in patients with IE caused by *Haemophilus* species or by fungi

6 Within 48 hours after initiation of specific ...crobial therapy, blood cultures should be ...ined to assess the efficacy of treatment Persistently positive blood cultures in spite of apparently appropriate treatment could indicate myocardial aortic root or distant abscesses tolerance of bacteria to antimicrobial agents or error in administration or dosage of antimicrobial agents

7 After antimicrobial therapy has been initiated careful attention should be directed to eliminating the possible portal of entry of the causative agent—for example poor dental hygiene or urinary tract infections with or without stones Dentulous patients with IE who are not critically ill should have dental x ray films and an oral surgery consultation so that necessary dental work can be performed *while* the patient is receiving treatment for IE Because of the association with inflammatory bowel disease and carcinoma of the colon patients with IE caused by *Streptococcus bovis* should have a proctoscopy and colon x ray studies while receiving antimicrobial therapy

8 If severe heart failure that is unresponsive to medical therapy ensues before completion of antimicrobial therapy prompt cardiac valve replacement should be considered Procrastination in an attempt to complete a course of antimicrobial therapy preoperatively will only increase the surgical mortality The hemodynamic status of the patient should be the most important factor in determining the timing of cardiac valve replacement

9 Before dismissal from the hospital patients and their families should receive adequate instructions in prophylactic measures for IE IE often has multiple and complex medical surgical and laboratory facets and patient education concerning prophylaxis is an important although frequently overlooked component

10 Follow up blood cultures should be obtained at 1 and 2 months after completion of antimicrobial therapy Relapses if they occur most often appear within the first 2 months after completion of treatment Infections caused by fungi, *Staphylococcus epidermidis* and fastidious microorganisms such as *Haemophilus* species may relapse later than 2 months

11 Finally physicians should respect the seriousness of IE and should resist the temptation to compromise in the duration and means of administration of therapy or to switch to less effective antimicrobial agents After initiation of therapy some patients with IE especially those with penicillin sensitive streptococcal infections, will experience a dramatic improvement in general well being and disappearance of fever These improvements should not be interpreted as an indication that the antimicrobial may be switched to orally administered agents or that the length of treatment may be shortened Symptomatic control of most hypersensitivity reactions should be attempted before a change is made to alternative therapy If major hypersensitivity reactions or other complications occur which cannot be controlled by symptomatic measures alternative therapy may be used. Clinicians should use only those accepted forms of alterna

Table II Treatment of penicillin sensitive viridans or nonenterococcal group D streptococcal infective endocarditis (MIC ≤ 0.1 μg/ml)

Treatment of patients not allergic to penicillin	*Alternative treatment of patients allergic to penicillin*
Procaine penicillin 1.2 million units IM q6h *plus* streptomycin 7.5 mg/kg IM q12h for 14 days	Cephalothin 1 g IV q4h for 28 days
or	or
Aqueous penicillin 20 million units IV per day for 28 days *plus* streptomycin 7.5 mg/kg IM q12h for the first 14 days of treatment	Vancomycin 7.5 mg/kg IV q6h for 28 days
or	
Aqueous penicillin 20 million units IV per day for 28 days	

Modification of method of Wolfe and Johnson [?]

Table IV Treatment of penicillin sensitive staphylococcal infective endocarditis (MIC ≤ 0.1 µg/ml)

Treatment of patients not allergic to penicillin	*Alternative treatment of patients allergic to penicillin*
Aqueous penicillin G 20 million units per day for 4 to 6 weeks	Cephalothin 1 g IV q4h or cefazolin 1 g IV or IM q6h for 4 to 6 weeks or Vancomycin 7.5 mg/kg IV q6h for 4 to 6 weeks

from nonenterococci (*S bovis*) by their growth in broth containing 6 5% sodium chloride

A very important characteristic of enterococci is that they are inhibited but not killed by penicillin alone A combination of penicillin (or ampicillin carbenicillin or ticarcillin) and aminoglycosides (streptomycin kanamycin gentamicin tobramycin or amikacin) acts synergistically against enterococci, and combined treatment is necessary for the successful therapy of enterococcal IE [illegible]

Table III outlines standard antimicrobial therapy for enterococcal IE Moellering and associates and others have shown that only about 60% of enterococci show synergy of bactericidal effect when incubated with penicillin plus streptomycin compared with penicillin alone [illegible] The approximate 40% of strains which are highly resistant to streptomycin (MIC > 2 000 µg/mL) do not show this synergistic effect The combined use of penicillin and gentamicin has been shown to result in synergistic bactericidal effect in vitro against most enterococci, including strains that are highly resistant to streptomycin Additionally combinations of penicillin and tobramycin ampicillin and gentamicin and vancomycin and gentamicin were found to act synergistically in vitro against highly streptomycin resistant strains of enterococci Hook and associates and Carrizosa and Kaye demonstrated in the experimental rabbit model of IE that the combination of penicillin and gentamicin was superior to the combination of penicillin and streptomycin in the treatment of infection caused by highly streptomycin resistant enterococci

The significance of streptomycin resistance in human IE is not clear At present insufficient data exist to indicate conclusively the s[illegible] of the penicillin gentamicin combination [illegible] penicillin streptomycin combination [illegible] treatment of streptomycin resistant entero[illegible] IE In patients with infections caused by [illegible] mycin resistant microorganisms, o[illegible] course might be to initiate therapy with [illegible] plus streptomycin and then measure the SBT [illegible] the SBT is low (<1 8) the dosage of [illegible] could be increased from 20 million units p[illegible] to 40 million units per day and the SBT [illegible] be remeasured If the SBT is still less th[illegible] gentamicin could be substituted for strep[illegible] and the SBT could be rechecked again [illegible] could then be made concerning the relat[illegible] apeutic advantage of streptomycin or g[illegible]cin

Some patients with enterococcal IE [illegible] require simultaneous antistaphylococcal th[illegible] for unrelated infections. In other [illegible] patients with acute IE such as that in [illegible] addicts may require initial antimicrobial th[illegible] for IE caused by either staphylococci or ent[illegible] cocci. In vitro studies have demonstrated [illegible] with nafcillin or oxacillin plus gentamicin [illegible] some strains of enterococci [illegible] However [illegible] and associates [illegible] in the experimental [illegible] model demonstrated that combinatio[illegible] cillinase resistant penicillin and gentamicin [illegible] not as effective as penicillin plus strept[illegible] gentamicin in the treatment of exper[illegible] enterococcal IE Until more data are av[illegible] nafcillin oxacillin or methicillin sho[illegible] substituted for penicillin G in the trea[illegible] enterococcal IE Likewise cephalospori[illegible] not be combined with streptomycin or gen[illegible] as a substitute for penicillin in the treatm[illegible] enterococcal IE [illegible] In these patients th[illegible] with three antimicrobial agents (that is pe[illegible] lin streptomycin and nafcillin) would be [illegible]able

Because experience with the use of al[illegible] to penicillin in patients with enterococcal [illegible] limited efforts should be made to con[illegible] use of penicillin in patients who have an e[illegible] history of previous "reaction" to pe[illegible] patients who experience minor hypersens[illegible] reactions during the course of treatment [illegible] penicillin In these patients symptoms [illegible] py may control minor hypersensitivity re[illegible] If penicillin therapy has to be interrupted [illegible]

vas 3% among our 68 patients who were treated with short term intramuscular therapy [21, 44] This is similar to that reported by Tompsett and [43] and by Wolfe and Johnson [4] Streptomycin associated toxicity is more likely to occur in he elderly and in patients who have abnormal renal function Streptomycin should be used with aution if at all in these patients Short term ntramuscular combined therapy should not be used in thrombocytopenic patients or in patients who have severe heart failure shock or other onditions in which there is presumed poor peripheral perfusion and possible decreased absorption of antimicrobial agents from sites of ntramuscular injection

Penicillin sensitive streptococcal IE may also be treated successfully with high dose intrave nous penicillin G alone The treatment should not be less than 4 weeks in duration In earlier clinical rials more than 50% of patients receiving 0 5 to 1 million units of penicillin per day for less than 2 weeks were treatment failures [4] When the losage of penicillin was increased to 14 to 16 million units per day for 10 to 14 days relapse rates of 15% were still encountered In two ecent retrospective studies no relapses occurred patients treated for 4 weeks or more with igh dose parenteral penicillin alone [5]

Based on data currently available it appears that the three regimens outlined above and in Table II are roughly equivalent in their cure rate The advantages of treatment for 2 weeks with ntramuscular antimicrobials over treatment for 4 weeks with intravenous antimicrobials or combined intramuscular and intravenous therapy or 4 weeks however are clear—namely short ned hospitalization period with reduced cost to patients more efficient use of hospital personnel and facilities and avoidance of potentially hazardous complications associated with the use of intravenous therapy A disadvantage of combined therapy is the small risk of streptomy cin associated vestibular toxicity This toxicity may be minimized by restricting the use of strep omycin in patients 65 years old or older or in patients with abnormal renal function and by ollowing patients closely for signs of developing estibular dysfunction Elderly patients and patients who have abnormal renal function hould be treated with penicillin G alone Anoth r disadvantage to the use of short term combined intramuscular therapy is the frequent intramuscular injections that are necessary In

Table III Treatment of penicillin resistant (enter ococcal) infective endocarditis (MIC $\geqq$ 0 1 µg/ ml)

Treatment of patients not allergic to penicillin	*Alternative treatment of patients allergic to penicillin*
Penicillin 20 to 40 million units IV per day or ampi cillin 12 g IV per day *plus* Streptomycin 7 5 mg/kg IM q12h or gentamicin 1 mg/kg IM or IV q8h for 4 to 6 weeks	Vancomycin 7.5 mg/kg IV q6h *plus* Streptomycin 7.5 mg/kg IM q12h or gentamicin 1 mg/kg IM or IV q8h for 4 to 6 weeks or Desensitize to penicillin

our experience however the intramuscular injec tions were generally well tolerated The tolerance was enhanced somewhat when the patient under stood that with this form of therapy mobility in the hospital is increased and the period of hospi talization is decreased

In patients who are unable to take penicillin because of hypersensitivity cephalosporins should be used with caution because of the possi bility of cross sensitivity reaction Cephalothin and vancomycin have been used successfully in the treatment of viridans and nonenterococcal group D streptococcal infections [3] [5] Desen sitization of patients to penicillin should be attempted only when alternative forms of thera py are impractical or unavailable

Until more data are available treatment of IE caused by other penicillin sensitive streptococci such as group A beta hemolytic streptococci group B streptococci *Streptococcus pneumoniae* and the like should be with high-dose penicillin (20 million units per day) intravenously for 1 month Patients who are unable to take penicillin may be treated for 1 month with cephalothin or vancomycin in dosages outlined in Table II

Penicillin resistant streptococcal IE—enterococci (MIC $\geqq$ 0 1 µg/ml)

The group D streptococci enterococcus group contains the organisms *S fecalis* and its two variants (zymogenes and liquefaciens) *S fae cium* and *S durans* Almost all of the enterococci that cause IE are *S fecalis* and most of these are of the variety liquefaciens Group D streptococci may be distinguished from viridans streptococci by their ability to grow in media containing bile and the enterococci may be further distinguished

authors have expressed doubts about the usefulness of cefazolin in the treatment of human IE due to S aureus[84] However, most clinicians believe that methicillin oxacillin nafcillin, cephalothin and cefazolin are roughly equivalent in their efficacy in the treatment of patients with IE due to S aureus Vancomycin may be used in patients who are unable to tolerate penicillin or cephalosporins

Table V outlines accepted antimicrobial therapy in patients with penicillin resistant staphylococcal IE Sabath and associates[85] recently describes staphylococci that are inhibited by low concentrations but are not killed by high concentrations of penicillinase resistant penicillins This disparity between MIC and MBC known as tolerance is of uncertain clinical significance More clinical experience is needed before conclusions can be made regarding the need for different therapeutic approaches to these patients with tolerant S aureus infections

The treatment of patients with endocarditis caused by penicillinase resistant S aureus is somewhat controversial That the antimicrobial therapeutic regimen should include a penicillinase resistant penicillin (nafcillin oxacillin or methicillin) a cephalosporin or vancomycin is unquestioned Controversy surrounds the desirability of the addition of other antimicrobial agents that are synergistic against S aureus when combined with the standard antistaphylococcal agents compared with the activity of penicillins or cephalosporins alone Sande and Johnson[89] demonstrated that the combination of penicillin and gentamicin acted synergistically in vitro against a strain of penicillin susceptible S aureus The combination of nafcillin and gentamicin showed synergy in vitro against penicillinase producing S aureus compared with the activity of nafcillin alone [92] In IE due to S aureus in experimental animals the organisms were eradicated more rapidly from cardiac vegetations when animals were treated with the combination of gentamicin and nafcillin than with nafcillin alone[90] Insufficient data exist to suggest that the combination of gentamicin and nafcillin should be used as standard therapy of human IE caused by S aureus The potential increased toxicity of the use of combined treatment should be considered and weighed against the theoretic benefit Gentamicin alone should not be used as therapy for IE due to S aureus

Mutant variants of S aureus emerge in [illegible] mental animals with IE caused by S [illegible] these animals are treated with gentamicin [illegible] and the use of gentamicin fails to steril[illegible] cardiac vegetation[93, 94]

A retrospective study of the use of single [illegible] and combination treatment with gentamic[illegible] patients with IE due to S aureus showed benefit from the use of the combination [illegible] single drug treatment[95] A cooperative prosp[illegible]tive study is currently under way compar[illegible] combination of nafcillin gentamicin therapy [illegible] the use of nafcillin alone in patients with pe[illegible]linase producing IE caused by S aureus

IE caused by methicillin resistant S [illegible] rare and treatment with vancomycin may b[illegible] necessary [illegible] Rifampin in combination with [illegible] antimicrobial agents may also prove useful in [illegible] treatment of methicillin resistant S aureus [illegible]tions[96]

S epidermidis is one of the most com[illegible] agents causing infection in patients with [illegible]thetic heart valves and cerebrospinal [illegible] shunts[9, 97] Whereas methicillin resistant [illegible] of S aureus are rare, S epidermidis resista[illegible] methicillin occurs commonly The freque[illegible] methicillin resistant S epidermidis isolate[illegible] been reported to range from 10 to 63%[illegible] er[101] reported that 63% of 27 isolates from pa[illegible] with prosthetic valve endocarditis or [illegible] cerebrospinal fluid shunts were resista[illegible] methicillin Archer made an extensive study of [illegible] vitro susceptibility and resistance patter[illegible] these 27 isolates Against methicillin res[illegible] isolates vancomycin cephalothin and cefa[illegible]dole had excellent activity against most isola[illegible] Among aminoglycosides tested gentamici[illegible] most active and no resistant cell populations [illegible] identified among susceptible isolates. R[illegible] identified among susceptible isolates [illegible] was the single most active agent against [illegible] isolates but high level resistance to rif[illegible] emerged in some isolates after 8 to 24 hou[illegible] incubation Because of the high frequen[illegible] methicillin resistance the initial regimen [illegible] treatment of IE caused by S epidermid[illegible] include agents that are active against methi[illegible] resistant microorganisms On the basis of [illegible] currently available cephalothin cefam[illegible] cefazolin alone or in combination with [illegible] agents chosen from among vancomycin r[illegible] and gentamicin appears to be the reg[illegible] choice for treatment of IE caused by meth[illegible]

patients subsequent resumption of therapy with penicillin is more likely to provoke serious reactions and alternative therapy should then be instituted In these patients or in patients with a history of anaphylaxis or other major hypersensitivity reaction to penicillin combinations of vancomycin streptomycin or vancomycin gentamicin may be used[6, 8, 77]

Combined penicillin aminoglycoside therapy is effective treatment for enterococcal IE No relapses occurred among 36 patients reported by Mandell and associates[61] and one relapse occurred among 30 patients reported by Geraci and colleagues[8] However adverse reactions associated with the use of aminoglycosides are common The high frequency of adverse and toxic reactions may be in part related to the average older age of patients with enterococcal IE (mean age 60 years) than that of patients with IE caused by other microorganisms (mean age 40 to 50 years)[78] Vestibular disturbances occurred in 10 to 30% of patients treated with streptomycin and 13 of 16 patients (81%) treated with gentamicin had abnormal values for serum creatinine (Wilkowske and associates unpublished data) Ototoxic reactions may also occur with the use of vancomycin and gentamicin Serum concentration of aminoglycosides and vancomycin should be measured frequently throughout the course of treatment Peak serum concentration of streptomycin 1 hour after administration of the dose should be adjusted to 10 to 15 µg/ml and should not exceed 20 µg/ml Peak 1 hour serum concentration of gentamicin should range from 3 to 5 µg/ml Peak 1 hour serum concentration of vancomycin should not exceed 20 µg/ml

Penicillin sensitive staphylococcal IE (MIC ≦ 0 1 µg/ml)

The course of IE caused by staphylococci is often acute and immediate antimicrobial therapy is required Staphylococcal endocarditis should be suspected in illicit intravenous drug abusers patients with prosthetic heart valves and when the suspected portal of entry is cutaneous or is associated with intravenous catheters Because more than 50% of community acquired and more than 80% of hospital acquired staphylococci produce penicillinase initial treatment of suspected staphylococcal IE should include a penicillinase resistant penicillin or a cephalosporin

Table V Treatment of penicillin resistant staphylococcal infective endocarditis (MIC ≧ 0 1 µg/ml)

Treatment of methicillin susceptible S aureus *and* S epidermidis *infections*	
Treatment of patients not allergic to penicillin	*Alternative treatment of patients allergic to penicillin*
Nafcillin oxacillin or methicillin 2 g IV q4h for 4 to 6 weeks	Cephalothin 1 g IV q4h or cefazolin 1 g IV or IM q6h for 4 to 6 weeks or Vancomycin 7.5 mg/kg IV q6h for 4 to 6 weeks
Treatment of methicillin resistant *S epidermidis* infections	
Cephalothin or cefamandole 1 g IV q4h or cefazolin 1 g IV q6h for 4 to 6 weeks	

Combinations of cephalosporins, vancomycin, gentamicin, rifampin may enhance killing of methicillin resistant *S epidermidis*

After the MIC is available only infections caused by staphylococci with penicillin MIC ≦ 0 1 µg/ml should be treated with penicillin G alone *S aureus* strains with penicillin MIC >0 1 µg/ml usually produce penicillinase and the production of penicillinase can be induced by the presence of penicillin Table IV outlines the usual therapeutic programs for IE caused by penicillin sensitive staphylococci A cephalosporin or vancomycin is an acceptable alternative to penicillin in patients who are unable to tolerate penicillin Treatment should be continued for a minimum of 4 weeks

Penicillin resistant staphylococcal IE (MIC ≧ 0 1 µg/ml)

Studies have been performed in experimental animals which have compared the efficacy of the most commonly used penicillinase resistant antistaphylococcal agents Egert and associates[1] reported that methicillin nafcillin and oxacillin were equally effective in experimental rabbit IE Carrizosa and associates[4] found that methicillin reduced more rapidly than did cefazolin or cephalothin the titers of *S aureus* in experimental aortic valve vegetations Cefazolin is more susceptible to inactivation by beta lactamase produced by *S aureus* than is cephalothin[83] and some

therapy is effective We believe that all patients with PVE should receive a minimum of 4 weeks of intravenous therapy with bactericidal antimicrobials

The use of anticoagulant therapy in patients with IE is controversial. Since the report by Thill and Meyer[11] published in 1947 many authorities have affirmed that anticoagulants are contraindicated in cases of endocarditis of natural or prosthetic valves because of the potential risk of central nervous system bleeding after thromboembolism [11-13] Because of the increased risk of thromboembolism with discontinuance of anticoagulant therapy in patients with prosthetic valves it would be desirable to continue the use of anticoagulants in patients with PVE provided that such therapy did not increase morbidity and mortality especially from central nervous system bleeding after thromboembolism We reported earlier that the use of anticoagulants did not increase morbidity or mortality in patients with PVE On the contrary the risk of major clinical central nervous system complications was increased and the mortality rate was higher when anticoagulants were discontinued Central nervous system complications occurred nine times more frequently when anticoagulants were discontinued or given in subtherapeutic dosage than when adequate anticoagulation was continued We believe that carefully controlled anticoagulant therapy should be continued cautiously in patients with PVE Patients should be observed closely for the development of central nervous system complications If such complications occur we agree with Karchmer and associates that use of anticoagulants should be discontinued temporarily If there is no clinical or laboratory evidence of intracranial hemorrhage anticoagulants may be reinstituted

Another difference between patients with PVE and those with natural valve IE is the necessity for a more aggressive surgical approach to patients with PVE We agree with Karchmer and co workers Richardson and associates and Saffle and colleagues that all patients with PVE who have moderate or severe heart failure that is unresponsive to medical therapy or in whom significant paravalvular leaks develop should undergo valve replacement early in the course of their illness Failure to act quickly with surgical intervention in these patients significantly increases the mortality rate The need for early cardiac valve replacement in all patients [illegible] early-onset PVE caused by staphylococ[illegible] been stressed by Richardson and associa[illegible]

The role of cardiac valve replacement in patients with IE

The role of cardiac valve replacem[illegible] patients with PVE and fungal IE has be[illegible] discussed briefly above During the antibi[illegible] congestive heart failure replaced seps[illegible] leading cause of death among patie[illegible] and most patients with IE who experie[illegible] failure do so because of hemodynamic c[illegible] quences of incompetent cardiac valves ex[illegible] bated by valvular infection In a retrosp[illegible] analysis of patients who underwent cardia[illegible] replacement because of heart failure caused b[illegible] IE we found the operative mortality to be d[illegible] related to the degree of functional heart fa[illegible] present at the time of operation [illegible] compared with a similar group of patients [illegible] IE who underwent cardiac valve replaceme[illegible] operative mortality was remarkably simi[illegible] that of patients with IE when the degree of [illegible] failure was the same at the time of [illegible] both groups of patients

In patients with functional Class IV [illegible] failure or with sudden-onset severe aortic [illegible] ciency associated with IE urgent cardia[illegible] replacement probably offers the only [illegible] survival. Cardiac valve replacement [illegible] successfully performed in these patients [illegible] active infection even when blood cul[illegible] positive in the immediate preoperative peri[illegible] Procrastination in cardiac valve replace[illegible] these patients in an attempt to stabi[illegible] failure by medical therapy [illegible] course of antimicrobial therapy [illegible] usually results in death from cardiac f[illegible] believe that the hemodynamic status of p[illegible] with IE should be the determining factor [illegible] timing of cardiac valve replacement rather [illegible] the activity of infection or the length of p[illegible] ative antimicrobial therapy

Richardson and associates sugges[illegible] patients with IE due to *S aureus* should [illegible] cardiac valve replacement We agree w[illegible] port that not all patients with IE caused [illegible] *aureus* require cardiac valve replacement [illegible] experience some patients with IE caused [illegible] *aureus* especially those with tricuspid [illegible] can be treated successfully with medical [illegible]

esistant *S epidermidis* The optimal combina ion of agents would depend on the results of in itro tests of MBC and SBT and of synergy tudies Until further data are available infec ions caused by methicillin *susceptible* strains of *S epidermidis* are probably best treated with a ingle agent (oxacillin nafcillin methicillin or ephalosporin)

The semisynthetic penicillins and cephalospo ins are generally well tolerated but adverse and oxic reactions occur Methicillin associated renal ailure and interstitial nephritis have been well locumented [°, 91] Other adverse reactions asso iated with the use of semisynthetic penicillins ave been granulocytopenia and hepati is [8, 10] Use of a cephalosporin may be asso iated with neutropenia and occasional renal ailure [106]

The mortality rate associated with staphylo occal IE is high The prognosis among heroin ddicts is relatively more favorable than that mong nonaddicts [95, 10, 10] The mortality rate of taphylococcal IE among nonaddicts usually xceeds 50% [6, 87, 109] Poor prognosis has been ssociated with an age of more than 50 years and he presence of underlying diseases—cardiac lisorders alcoholism cirrhosis and diabetes nellitus The rate of survival from staphylococcal ndocarditis is higher if the patient lives long nough to receive at least 2 weeks of antimicro ial therapy

Treatment of IE caused by other microorganisms

The antimicrobial therapy of IE caused by ther microorganisms depends on isolation and lentification of the offending organism and the esults of in vitro susceptibility tests of MIC ABC and SBT Susceptibility testing may be ifficult or impossible with some fastidious gram egative bacilli especially *Haemophilus* species Most *Haemophilus* species are highly susceptible o ampicillin and IE caused by these microorgan isms may be treated successfully with ampicillin dministered intravenously for 3 weeks If in vitro usceptibility tests with this organism cannot be erformed empiric therapy with ampicillin or moxicillin may be used Clinical parameters uch as disappearance of fever and return of ppetite serve as guidelines to the effectiveness of herapy in such cases Infections caused by micro rganisms other than those streptococci staphy lococci and *Haemophilus* species described above should be treated a minimum of 4 weeks Most authorities believe that patients with culture negative IE should be treated with regimens that are effective against enterococcal IF [2]

Fungal endocarditis

Candida species and *Aspergillus* species are the most common causes of fungal IE Of the two IE due to *Candida* occurs more commonly and is seen most frequently in association with drug addicts [1] IE caused by *Aspergillus* occurs most often as a complication of cardiac valve replacement [30, 9, 91] The course of fungal endocar ditis is usually subacute or chronic and is charac terized by the frequent occurrence of arterial embolization of large friable fungal vegetations Treatment of fungal IE with amphotericin B or 5-fluorocytosine or both is frequently unsuccess ful and antifungal therapy combined with cardiac valve replacement is necessary in most cases [8, 3]

Prosthetic valve endocarditis

During the past 7 years prosthetic valve endo carditis (PVE) accounted for approximately 17% of the total number of cases of IE seen at the Mayo Clinic Because of differences in microbio logic causation expression of clinical syndrome treatment and prognosis patients with PVE should be considered separately from patients with natural valve endocarditis Infections that occur early (less than 2 months after operation) are most often caused by *S epidermidis S aureus* gram negative bacilli or diptheroids and are associated with a very high mortality rate—more than 80% [3] Late onset infections (more than 2 months after operation) are asso ciated with a better prognosis—38% mortality rate in one study—than early onset infection and are caused by those microorganisms that most often cause natural valve endocarditis

The antimicrobial therapy of patients with PVE is similar to that of patients with natural valve IE One major exception however is the treatment of patients with penicillin sensitive streptococcal PVE These patients should not be treated with short term intramuscular therapy In our experience 4 weeks of intravenous aqueous penicillin G 20 million units per day for 4 weeks combined with streptomycin 7 5 mg /kg intra muscularly every 12 hours for the first 2 weeks of

nent alone These patients should be followed losely and if heart failure or other signs of hemodynamic deterioration appear considera ion should be given to urgent cardiac valve eplacement

In general the same guidelines for cardiac alve replacement in the usual population apply o drug addicts A special situation exists in drug addicts who have recurrent infection of the tricus id valve with gram negative bacilli that are esistant to multiple drugs notably *Serratia narcescens* and *Pseudomonas* species In these ts excision of the tricuspid valve without mmediate artificial valve replacement may be necessary[1 8] Although progressive right sided heart failure may subsequently develop in these patients some patients have tolerated the absence of a tricuspid valve for a surprisingly long ime

stellate ganglionectomy preceding an experimental coronary occlusion reduced the incidence of acute cardiac deaths, indeed, in two groups of ten dogs each ventricular fibrillation occurred in five neurally intact animals but in only one previously sympathectomized dog In addition the authors advanced the remarkable hypothesis that the nervous pathways which carry the painful impulses in angina may perhaps act as a reflex arc which carries pain and other impulses to the heart which are deleterious to its function [7] A recent and appreciable review[8] pointed out that Cox and Robertson s data if analyzed according to current criteria fail to attain statistical significance Had those authors known the future fashion of a p value they would have certainly performed two more experiments for the sake of a p value $< 0\ 05$

Myocardial ischemia and autonomic disturbance The work by Pantridge s group[9, 10] represents a clinical milestone It was found that the vast majority of patients had signs of autonomic disturbance within the first 30 minutes from the onset of acute myocardial infarction, signs of excessive sympathetic activity were more frequent in cases of anterior infarction whereas signs of vagal overactivity were more frequent in inferior infarctions Thus it was suggested that different specific mechanisms likely to be neural were involved in either anterior or inferior infarctions independently of common denominators such as pain emotion or pump failure

a Increased efferent sympathetic activity Classically an increased sympathetic activity in the course of a visceral disease is thought to result from brain mechanisms like pain and emotion or from peripheral reflex influences

The work by Littler and associates[11] on direct arterial pressure and electrocardiograms recorded in ambulatory patients with angina pectoris showed that electrocardiographic changes typical of ischemic attacks can be accompanied by hypertension and tachycardia before the onset of pain The literature associating angina and increases in arterial pressure and heart rate is extremely abundant however the novelty of that report was that pressor events were independent of emotion and pain and therefore the most likely cause was a pressor reflex from the heart This hemodynamic picture has been particularly well documented in the more recent studies by Maseri s group[12]

There is increasing evidence that excitation of afferent fibers from the heart traveling in the cardiac sympathetic nerves may have an important role in determining the reflex sympathetic activity returning to the heart and affecting cardiac events these reflexes can be properly defined as cardio cardiac sympathetic reflexes[14 16] The excitation of cardiac sympathetic afferent fibers is also capable of reflexly inhibiting the activity of efferent vagal cardiac fibers through a sympatho vagal reflex[1] Thus the excitation of sympathetic cardiac afferent fibers could affect the heart and stimulate its function through an increased sympathetic discharge and a synergistically reduced vagal restraint

Cardiac sympathetic sensory endings, subserved by myelinated[18] or unmyelinated fibers[1] are mechanoreceptors normally excited by mechanical events[18 19] but their activity can be further enhanced by chemical substances like bradykinin[20] which are known to be released in the ischemic heart The hypothesis is that mechanical abnormalities of the ischemic myocardium and chemical factors possibly in sequence underlie a crescendo excitation of spontaneously active sympathetic afferent fibers leading to pressor reflexes and above a given threshold to pain When pain supervenes in the course of a cl... ischemic episode a further rise in arterial pressure usually occurs[11 13]

This sympathetic overactivity could have in principle opposite consequences On the one hand it might beneficially attempt to maintain normal ventricular function through an increased contractility[21] thus opposing ventricular dilatation and vagally mediated depressor reflexes On the other hand deleterious effects are strongly suggested by numerous facts The traditional view is that an increased sympathetic activity profoundly alter the balance between oxygen supply and demand especially in the jeopardized myocardium In electrophysiological terms it would increase the electrical inhomogeneity which already results from cellular damage through mechanisms of altered automaticity and dispersion of the refractory period

That sympathetic cardio cardiac reflexes may influence occurrence of arrhythmias in the ischemic heart has recently been demonstrated in experimental animals The interruption of the afferent sympathetic limb of the cardio-cardiac reflex by a section of dorsal roots from the ...

\eural mechanısms ın lıfe threatenıng

ı ıı

\rrhythmıas may be due to abnormalıtıes of ıutomatıcıty of conductıon or to a combınatıon ıf both[1] The vısceral nervous system through ıts ympathetıc and parasympathetıc outflows can nodıfy both of these propertıes and quıte com ılex ınteractıons are lıkely to occur

Dısturbances ın cardıac rhythm are quıte com non but there ıs a major dıfference between enıgn and lıfe threatenıng arrhythmıas

It ıs currently held[2,3] that any condıtıon ncreasıng the electrıcal ınhomogeneıty of cardıac nuscle renders ıt more vulnerable to arrhythmo enıc mechanısms ıncludıng the autonomıc nfluences Indeed ıt seems lıkely that some lectrıcal ınhomogeneıty should be necessary ıther orıgınatıng ın the myocardıum ıtself or due o ınhomogeneıty ın the ınfluences playıng upon † to create those condıtıons usually assocıated ıth lıfe threatenıng arrhythmıas

It ıs the purpose of thıs brıef revıew to analyze ome clınıcal and pathophysıologıcal states often haracterızed by lethal arrhythmıas and ın whıch utonomıc mechanısms seem to play a major role hıs role ın the dıfferent condıtıons ıs lıkely to ange from what seems to be an aggravatıng ıctor as occurs durıng acute myocardıal ısche ııa to what seems to constıtute a more substan ıal pathogenetıc mechanısm or at least a crucıal rıgger as ıs the case of the long QT syndrome

In thıs revıew the underlyıng cellular electro physıology wıll be only alluded to whıle emphasıs wıll be placed on the over all autonomıc ınfluences ın an attempt to analyze the genesıs of theır changes and the role of theır effects ın the occurrence of lıfe threatenıng arrhythmıas On the basıs of thıs analysıs we shall also advance some logıcal therapeutıc ımplıcatıons

1 Neural mechanısms ın arrhythmıas assocıated wıth myocardıal ıschemıa

It was the merıt of surgeons to have fırst apprecıated that some crucıal ınteractıon could occur between myocardıal ıschemıa and the nerv ous system to cause lethal arrhythmıas Indeed thıs concept happened to develop durıng the attempts at solvıng another problem that of the relıef of angınal paın Apparently Françoıs Franck ın 1899 proposed a cervıco thoracıc sym pathectomy for the ınterruptıon of the nocıcep tıve path from the heart (quoted by Danıelopo lu)

In 1916 Jonnesco followed that suggested but the ınterventıon was judged physıologıquement ınadmıssıble by Danıelopolu[4] as ın hıs opınıon ıt would also ınterrupt the efferent cardıac sym pathetıc supply thought to be a vasodılator of the coronary arterıes thus enhancıng the rısk of coronary spasm then as fashıonable as nowadays Lerıche and co workers shared for some years Danıelopolu s vıew but eventually felt as a result of both clınıcal and experımental work that a hıgh thoracıc sympathectomy could be benefıcıal ın cases of angına pectorıs as such a procedure seemed to attenuate the tendency to ventrıcular fıbrıllatıon

A few years later ın 1936 Cox and Robertson stressed agaın on much better grounds that

arrhythmias are the experiments performed by Verrier Lown and their associates[39,40] They found that hypothalamic stimulation not only promotes fibrillation in animals with acute myocardial ischemia[39] but also lowers the threshold for ventricular fibrillation in intact animals[40] These effects on ventricular vulnerability could be obtained in vagotomized animals independently of changes in heart rate or in blood pressure, thus they were mediated by changes in sympathetic activity

Electrical stimulation applied directly to the nerves going to the heart has also yielded a considerable amount of information Stimulation of the stellate ganglia lowers the threshold for ventricular fibrillation decreases ventricular refactoriness and may produce ventricular arrhythmias

However information obtained using the technique of electrical stimulation although valuable in identifying neural circuits and in showing the effects of a massive activation of nerve fibers present in the stimulated nerves should be interpreted with caution because of the artificial nature of the stimulus A useful way to integrate these notions is to study the effects of denervation which explores the importance of the continuos neural activity of vagal and sympathetic nerves This goal was initially achieved by studying the effects of bilateral stellectomy recently also unilateral stellectomy has been employed with partly unexpected results For instance among other effects bilateral stellectomy increases the threshold for ventricular fibrillation on the other hand while left stellectomy is attended by a major increase in the ventricular fibrillation threshold right stellectomy paradoxically results in a striking fall in the threshold The antifibrillatory effect of left stellectomy has potentially profound clinical implications and will be further discussed in the section on therapy The paradoxical arrhythmogenic effects of right stellectomy have been now repeatedly confirmed in several experimental conditions

The role of vagal activity in ventricular arrhythmogenesis is still unclear The traditional view that the vagus exerts little or no influence on ventricular electrical properties was initially challenged by Kent and Epstein who found that vagal stimulation significantly increased the threshold for ventricular fibrillation in both the
normal and the ischemic myocardium
quently Verrier and associates found th
activation exerts a protective effect wh
sympathetic activity is elevated and is
without effect when the adrenergic input
heart is largely prevented by beta adre
blockade A possible basis for this ir er
would be represented by an activation of
rinic presynaptic receptors modulatin
lease of catecholamines The most likely
tomic site for the interaction is the His-Pu
system which is richly innervated by vag
sympathetic neuroeffector endings. The m
lar basis for this adrenergic-cholinergic
nism has recently been indicated by Wat
and Besch[53] as possibly being mediated by
AMP cyclic GMP interactions

However, a correct understanding of
vagal effects on arrhythmias is made diffic
the fact that changes in vagal activity are a
panied by profound changes in heart rate
very importantly influence ventricular arr
mias For instance the suggestion that
phenylephrine induced suppression of ventr
arrhythmias depends upon the reflexly in
increase in vagal activity is not supported
recent study Indeed Weiss and colleag
using atrial pacing have shown that the
rhythmic effect of phenylephrine is mostly d
the attendant slowing in heart rate

In the next paragraphs sympathetic and
arrhythmogenic influences will be reviewed
occurring in the following conditions (1) ps
logic stress (2) exercise and (3) sleep The
QT syndrome will then be considered as a p
liar condition in which neural mechanism
lead to lethal arrhythmias

1 Psychologic stress The relationship
tween psychological factors cardiac arrhyth
and sudden death has been dealt with in
reviews we will only discuss here the evid
that the critical link for this relationship
sented by the sympathetic nervous system

There is abundant clinical literature of
anecdotal type showing the occurrence of ca
arrhythmias and even sudden death duri
tionally important events However the
evidence comes as is often the case from ex
mental studies

Verrier Lown and their associates have
the effect of a psychologically stressful e

cervical segment to the fifth thoracic segment was capable of reducing the number of ectopic beats associated with short lasting coronary occlusion[25]

From a clinical point of view it is important to mention the high incidence of ventricular tachyarrhythmias in patients with anterior myo cardial infarctions as was shown by Pantridge s group[9, 6]

b Increased efferent vagal activity As was first shown by Pantridge s group soon after infe rior myocardial infarction there is a very high incidence of bradycardia or hypotension or both which often seems to act as a prelude to ven tricular fibrillation Likewise during transient episodes with electrocardiographic signs of myo cardial ischemia accompanied by pain or not hypotension and bradycardia can occur or hypo tension alone can occur without the tachycardia expected from baroreflex deactivation[13]

The laboratory notion of vagally mediated depressor reflexes from the heart is an old one deriving from the experiments with veratrum alkaloids of von Bezold and Hirt It was not until a hundred years later however that depres sor reflexes with vagal afferent fibers were studied adequately with respect to their possible patho physiological role during experimental coronary occlusion[3, 4] distension of cardiac chambers and increase in coronary pressure

These depressor reflexes act through the excita tion of the vagal and the inhibition of the sympa thetic outflow However what appears as a dan gerous clinical reality does not easily fit in the simple scheme provided by some laboratory find ings indicating that an increased vagal activity reaching the heart especially if associated with a reduction of sympathetic tone should increase electrical stability and raise the fibrillation threshold[3] However the antiarrhythmic effects of the vagus may be augmented or reversed by its profound influence on heart rate in the setting of acute myocardial ischemia[3]

c The sympatho vagal interaction Adminis tration of atropine for management of bradycar dia has been reported to often unmask a simulta neous sympathetic overactivity This is indeed not surprising The left ventricle has a rich senso ry innervation with afferent fibers running both in the vagi and in the sympathetic nerves A mechanical abnormal event with or without the sensitizing contribution of chemical substances has the potentiality of eliciting the following set of reflexes sympatho sympathetic sympatho vagal vago vagal and vago sympathetic Which of these reflexes will prevail will depend on the type of sensory endings excited on the specific nature and location of the abnormal stimulus and on the complex integrating connections in the brain

Yet a frequent pathophysiologic event could be that of an increased vagal *and* sympathetic efferent activity as the result of prevailing vago vagal and sympatho sympathetic reflexes Such a common event would weaken the old conception of vagal and sympathetic outflows working in a sort of reciprocal arrangement Bergamaschi[3] has recently shown that after ligation of the anterior descending coronary artery the simultaneous stimulation of cardiac vagal and sympathetic efferent fibers produced a greater incidence of severe arrhythmias including ventricular fibrilla tion than the separate stimulation of either efferent system

2 Neural mechanisms in arrhythmias not associated with myocardial ischemia

There is a definite experimental proof that sympathetic and vagal activities can also elicit arrhythmias in the absence of any demonstrable degree of myocardial ischemia The sympathetic and vagal arrhythmogenic effects have been stud ied primarily by stimulating or interrupting the neural paths to the heart or by injecting various drugs that interfere with autonomic activity

Electrical stimulation of various areas of the brain has resulted in a diversity of cardiac arrhythmias[33, 4] mostly mediated by activation of the sympathetic nervous system Manning and Cotten showed that the simultaneous increase in both sympathetic and vagal activity was par ticularly detrimental These arrhythmias occur during stimulation and after cessation of the stimulation Evans and Gillis[36] have concluded that arrhythmias produced during the stimula tion are predominantly mediated by the sympa thetic nerves while the others are primarily dependent upon a vagal reflex discharge Ar rhythmias and electrocardiographic changes in duced by brain stimulation may represent an interesting model for arrhythmias and repolariza tion abnormalities often accompanying cerebro vascular accidents.[7, 3]

Relevant to the problem of life threatening

ischemic myocardium may precipitate arrhythmias In particular the rebound of REM sleep which occurs as a consequence of REM sleep deprivation or after withdrawal of drugs such as barbiturates may be quite arrhythmogenic in an ischemic heart[7]

On the other hand there is evidence that quiet sleep may represent a state of even greater risk. During quiet sleep the QT interval is prolonged as compared to REM sleep[73 74] vulnerability to arrhythmias in hypoxic kittens increases[75] and ventricular fibrillation is more rapidly induced by acute ischemia in pigs[76] Skinner and co workers[76] have also shown that pigs with an acute myocardial infarction have more cardiac arrhythmias during sleep as compared to their awake state

Another important clinical condition (8 000 to 10 000 victims per year in the U S) in which lethal cardiac arrhythmias may occur during sleep is the Sudden Infant Death Syndrome The typical clinical story is that of a healthy infant age two to four months put to sleep for a nap or for the night and found dead shortly thereafter or the next morning Although the cause or more probably the causes of these sudden deaths have not been clarified the possibility has recently been proposed that at least some cases of Sudden Infant Death Syndrome might depend upon an abrupt sympathetic discharge taking place through an asymmetrically developed sympathetic innervation of the heart with dominance of left sided nerves

The long QT syndrome The idiopathic long QT syndrome (LQTS) is characterized by prolongation of the QT interval frequent alternation of the T wave and syncopal episodes due to ventricular fibrillation eventually resulting in the sudden death of most affected individuals [9] Crucial for the understanding of the pathogenetic mechanisms is the clinical observation that the syncopal episodes almost always follow an emotional or a physical stress This tight association between emotions such as fear or anger and ventricular fibrillation undoubtedly contributes to the uniqueness of this clinical entity

A most likely pathogenetic mechanism suggested by clinical and experimental data is a congenital imbal [illegible] between right and left cardiac sympath [illegible] with a left dominance Alternatively [illegible] likely the basic defect may be an unk [illegible] ardiac abnormality decreasing electrical stability and sensiti [illegible] myocardium to sympathetic discharges In [illegible] case, there is no doubt that the ventric [illegible] tachyarrhythmias which lead the LQTS p [illegible] to death depend upon sudden increases in [illegible] thetic activity mostly through the domina [illegible] stellate ganglion

Data regarding the pathogenesis of the l [illegible] syndrome have been gathered mostly by [illegible] lation of the sympathetic nervous system [illegible] experimental animals right stellectomy [illegible] produces a relative dominance of left card [illegible] sympathetic nerves results in (1) prolonga [illegible] the QT interval[47 8] (2) increase in ve [illegible] arrhythmias during myocardial ischemia,[0] ex [illegible] cise [9] and emotion[41 6] (3) lowering of the thr [illegible] old for ventricular fibrillation and (4) [illegible] in ventricular excitability[4] Furthermor [illegible] patients with the long QT syndrome alterna [illegible] the T wave has been elicited by blockade of [illegible] right stellate ganglion[83] and has been supp [illegible] by blocking the left stellate ganglion[4] [illegible] tion of the T wave and ventricular arrhythm [illegible] have been produced in animals [9] and in ma [illegible] stimulation of the left stellate ganglion.

The understanding of the mechanisms [illegible] ing ventricular fibrillation has dictated a [illegible] therapeutic approach to the long QT synd [illegible] beta adrenergic blocking agents or left stel [illegible] my The most recent evaluation of the effe [illegible] therapy in the long QT syndrome [1] indicates th [illegible] in over 500 patients beta blockers reduce [illegible] mortality rate from 78% (untreated patie [illegible] 6% At the present time left stellectomy [illegible] the first time in 1970 by Moss and McD [illegible] has been performed in 20 patients all refract [illegible] beta blockers resulting in the suppression [illegible] complete or almost complete of the sy [illegible] attacks With other therapies the mortali [illegible] is still around 50% The available data [illegible] that the first choice treatment is repre [illegible] beta blockers at full dose should howev [illegible] syncopal attacks continue left [illegible] becomes mandatory

3 Therapeutic implications

Attempts to reduce the incidence of li [illegible] ening arrhythmias in patients at high r [illegible] sudden cardiac death should be directed [illegible] those factors which may induce or increase [illegible] diac electrical instability The overwhel [illegible]

ment Dogs were exposed to two different environments a cage in which the animals were left undisturbed and a sling in which they received a transthoracic shock for three consecutive days On days 4 and 5 the effects of the two environments were compared, as the dogs entered the sling they became restless exhibited somatic tremor and their heart rate increased markedly Under this condition it was found that the threshold for repetitive extrasystoles which was considered as a marker of cardiac vulnerability was reduced by 50% That this increase in vulnerabil was mediated by the sympathetic nervous system was indicated by the fact that it was completely prevented by a beta adrenergic blocking drug[58] Furthermore when dogs with a recent myocardial infarction and free of arrhythmias were reexposed to the aversive environment ventricular arrhythmias including ventricular tachycardia occurred these phenomena disappeared when the animals were returned to the quiet

Another hint as to the arrhythmogenic role of stress comes from the observation[60] that farm pigs sufficiently adapted to the laboratory are less prone to ventricular fibrillation after coronary occlusion In this case however beta blockade with propranolol did not afford any protection The possibility has been raised [1] that in this study blockade of beta adrenergic cardiac innervation was inadequate

2 Exercise Exercise can increase the incidence of ventricular arrhythmias not only in patients with coronary heart disease but also in normal subjects[6] Most of these arrhythmias occur in the post exercise recovery period

It is common knowledge that during exercise there are a simultaneous increase in sympathetic tivity and a withdrawal of vagal tone upon cessation of exercise vagal activity immediately resumes while the cardiac effects of catecholamines are still present

Three recent studies have provided evidence on the relationship between the sympathetic nervous system and exercise induced cardiac arrhythmias In dogs performing submaximal exercise on a treadmill some arrhythmias occurred in a small percentage of intact animals and in an equally percentage of animals with left stellectomy arrhythmias were absent after bilateral stellectomy However they were markedly increased after right stellectomy with the left stellate ganglion intact [9] In another study in dogs whose hearts were completely denervated with the exception of the ventrolateral cardiac nerve which originates from the left stellate ganglion arrhythmias were often produced by exercise [3] Likewise in 75 patients who had undergone unilateral or bilateral stellectomy as a treatment of Raynaud s syndrome and who were studied with submaximal exercise on a treadmill [4] exercise induced ventricular arrhythmias appeared in a very small percentage of control subjects with intact stellate ganglia and in patients with left stellectomy These arrhythmias were entirely absent in patients who had a bilateral stellectomy and occurred in a considerable proportion of patients with right stellectomy These studies have shown the important role of cardiac sympathetic nerves in the genesis of arrhythmias during exercise and have indicated the particular arrhythmogenic potential of left sided sympathetic nerves especially when a condition of sympathetic imbalance is created

Another mechanism potentially relevant for the development of arrhythmias during exercise in patients with coronary heart disease is represented by the fact that during exercise coronary flow is still restricted by sympathetic vasoconstrictor tone and that this tonic vasoconstriction is dependent upon nerve fibers passing through the left stellate ganglion Indeed after left stellectomy coronary flow during exercise is higher compared to control condition suggesting that the sympathetic activity may limit the vasodilation of the coronary bed secondary to increased metabolic demands

3 Sleep The effect of sleep on cardiac arrhythmias is still controversial Clinical findings ranged from a complete abolition or an amelioration of cardiac arrhythmias during sleep [5] to an exclusive occurrence of arrhythmias during sleep [6]

REM sleep because of its association with bursts of autonomic activity [6] has been considered for a while the stage of sleep in which the heart is most vulnerable Transient elevations in blood pressure and heart rate occur during REM sleep[69, 70] suggesting that sympathetic bursts may be superimposed on the tonic decrease in sympathetic activity [0, 11] These changes may decrease the electrical stability of the heart and in an

ischemic myocardium may precipitate arrhythmias In particular, the rebound of REM sleep which occurs as a consequence of REM sleep deprivation or after withdrawal of drugs such as barbiturates may be quite arrhythmogenic in an ischemic heart [72]

On the other hand there is evidence that quiet sleep may represent a state of even greater risk During quiet sleep the QT interval is prolonged as compared to REM sleep [73,74] vulnerability to arrhythmias in hypoxic kittens increases [75] and ventricular fibrillation is more rapidly induced by acute ischemia in pigs [76] Skinner and co workers [76] have also shown that pigs with an acute myocardial infarction have more cardiac arrhythmias during sleep as compared to their awake state

Another important clinical condition (8,000 to 10 000 victims per year in the U S) in which lethal cardiac arrhythmias may occur during sleep is the Sudden Infant Death Syndrome The typical clinical story is that of a healthy infant age two to four months put to sleep for a nap or for the night and found dead shortly thereafter or the next morning Although the cause or more probably the causes of these sudden deaths have not been clarified the possibility has recently been proposed that at least some cases of Sudden Infant Death Syndrome might depend upon an abrupt sympathetic discharge taking place through an asymmetrically developed sympathetic innervation of the heart with dominance of left sided nerves

The long QT syndrome The idiopathic long QT syndrome (LQTS) is characterized by prolongation of the QT interval frequent alternation of the T wave and syncopal episodes due to ventricular fibrillation eventually resulting in the sudden death of most affected individuals [78] Crucial for the understanding of the pathogenetic mechanisms is the clinical observation that the syncopal episodes almost always follow an emotional or a physical stress This tight association between emotions such as fear or anger and ventricular fibrillation undoubtedly contributes to the uniqueness of this clinical entity

A most likely pathogenetic mechanism suggested by clinical and experimental data [81] is a congenital imbalance between right and left cardiac sympathetic nerves with a left dominance Alternatively though less likely the basic defect may be an unknown intracardiac abnormality decreasing electrical stability and sensitizing myocardium to sympathetic discharges. In any case there is no doubt that the ventricular tachyarrhythmias which lead the LQTS patients to death depend upon sudden increases in sympathetic activity mostly through the dominant stellate ganglion

Data regarding the pathogenesis of the long QT syndrome have been gathered mostly by manipulation of the sympathetic nervous system. In experimental animals right stellectomy which produces a relative dominance of left cardiac sympathetic nerves results in (1) prolongation of the QT interval [47,82] (2) increase in ventricular arrhythmias during myocardial ischemia [4] exercise [49] and emotion [47,64], (3) lowering of the threshold for ventricular fibrillation [4] and (4) increase in ventricular excitability [4] Furthermore patients with the long QT syndrome alternation of the T wave has been elicited by blockade of the right stellate ganglion [3] and has been suppressed by blocking the left stellate ganglion Alternation of the T wave and ventricular arrhythmias have been produced in animals and in man by stimulation of the left stellate ganglion

The understanding of the mechanisms triggering ventricular fibrillation has dictated a logical therapeutic approach to the long QT syndrome beta adrenergic blocking agents or left stellectomy The most recent evaluation of the effect of therapy in the long QT syndrome indicates that in over 500 patients beta blockers reduce the mortality rate from 78% (untreated patients) to 6% At the present time left stellectomy used for the first time in 1970 by Moss and McDonald has been performed in 20 patients all refractory to beta blockers resulting in the suppression or the complete or almost complete of the syncopal attacks With other therapies the mortality rate is still around 50% The available data indicate that the first choice treatment is represented by beta blockers at full dose should however syncopal attacks continue left stellectomy becomes mandatory

3 Therapeutic implications

Attempts to reduce the incidence of life-threatening arrhythmias in patients at high risk of sudden cardiac death should be directed against those factors which may induce or increase cardiac electrical instability The overwhelming

dence pointing to the crucial role of the cardiac innervation as the precipitating factor implies that measures which prevent or antagonize sympathetic or parasympathetic effects might prove beneficial

Beta adrenergic blocking drugs have gained wide clinical acceptance as antiarrhythmic agents Along the same line of thought surgical ablation of the cardiac sympathetics has recently been suggested as a possible therapeutic procedure Both approaches will be briefly reviewed Finally the possibility will be considered of pharmacological blockade of parasympathetic efferent activity

1 Beta adrenergic blocking agents That beta adrenergic blocking agents may be effective in treating or preventing life threatening arrhythmias in coronary patients is suggested by animal experiments which show that these agents seem to reduce the number of ventricular dysrhythmias resulting from coronary occlusion [6]

The effectiveness of these compounds in clinical dysrhythmias is incompletely documented however Taggart and colleagues [7] by monitoring the electrocardiogram for prolonged time in subjects performing their daily tasks have observed that beta blockade is highly effective in protecting against emotionally induced arrhythmias in both normal subjects and in patients with coronary heart disease Yet the clinical condition in which prompt administration of beta adrenergic antagonists may in principle be most advantageous acute myocardial infarction with disrhythmias generally requires urgent therapeutic measures thus precluding studies which satisfy the stringent rules of clinical trials The majority of investigators [8, 9] who have tried intravenous administration of various beta blockers in patients with acute myocardial infarction have found that no more than 50% of patients treated responded favorably the drugs being most effective in sinus tachycardia and ventricular premature beats and least effective for reversing atrial fibrillation It is worth emphasizing furthermore that the benefit risk balance of administrating a beta blocker to patients under such as dangerous condition as acute myocardial infarction is always difficult to predict and to assess the outcome in the individual case will largely depend on the net balance between further depression of sympathetic dependent cardiac contractility on one side and an improvement in pumping function and decreased risk of ventricular fibrillation by reversion of tachyarrhythmias on the other side

It should also be considered in view of the evidence summarized previously suggesting that dysrhythmias in early myocardial infarction may be mediated by either the cardiac sympathetics or the vagi according to the infarction site (anterior versus inferior) that more definite advantages may be obtained by limitating the use of beta blockade to patients with anterior myocardial infarction

A further application of beta blockers which lends itself to a better though extremely laborious testing is in preventing sudden death and the recurrence of cardiac events when given over the long term following myocardial infarction A few trials recently completed [90] have shown favorable results of the long term administration of the beta adrenergic blocking agents alprenolol and practolol The practolol study[59, 90] indicated that the protective effect of the drug consisting in a significant reduction of over all mortality rate and in sudden death was most consistent in those patients whose original infarcts were localized anteriorly again a clear reference to Pantridge s work Because of the severe side effects of practolol continuation of its favorable results is being sought in other trials presently under way and by using other beta blockers

The striking favorable effects of beta blocking therapy in preventing lethal arrhythmias in the long QT syndrome[79, 81] have already been summarized in the preceding section

2 Left sympathectomy An alternative procedure for preventing or limiting sympathetic arrhythmogenic influences upon the heart is represented by cardiac sympathectomy Evidence from animal experiments that we have summarized above clearly shows that the following beneficial results can be obtained even when cardiac sympathectomy is limited to the left side and only consists in left stellectomy Indeed left stellectomy reduces the incidence of ventricular arrhythmias associated with short lasting coronary occlusion it produces a marked increase in the threshold for ventricular fibrillation it prolongs the ventricular refractory period [6] it increases the capability of the coronary bed to dilate it does not reduce cardiac performance during exer

influences an approach that has been neglected for years perhaps as a consequence of the dominant role played by the so called pump physiology in the traditional approach to cardiovascular disease

This new approach is already reflected in useful therapeutic measures to correct life threatening arrhythmias both in frequently occurring cases of cardiac ischemia and in the rarer conditions in which ischemia is absent it represents the rationale of current promising attempts to provide prevention of myocardial infarction and sudden death Hopefully it will stimulate further research which may lead to more sophisticated and improved therapeutic strategies in the near future

Case presentation

Dr Olney The patient a 77 year old woman was first seen at the Mayo Clinic on November 30 1977 with a six month illness characterized chiefly by malaise fatigue anorexia weight loss and fever Her previous medical history included central retinal vein occlusion in 1976 hypertension of ten years duration a heart murmur known for 20+ years and hysterectomy oophorectomy in 1956 She was currently taking Dyazide one capsule per day for her hypertension

During the preceding six months she had consulted several local physicians and was given a variety of tentative diagnoses for her illness including upper respiratory infection pneumonia pulmonary edema and urinary infection Documentation of these diagnoses was lacking and therapies directed at the conditions failed to appreciably alter her apparently deteriorating well being The physical findings described at various times during this period included blood pressure recording ranging from 110/70 to 190/80 mm Hg and a grade 2/6 systolic ejection murmur Some of the laboratory test results were a white blood cell count of 16 200/cu mm sedimentation rate 40 mm/hr Westergren blood glucose 150 to 212 mg/dl normal urinalyses and normal chest roentgenogram

On November 30 1977, she w to

Rochester Methodist Hospital By this time she was recorded as having had a 20 kilogram weight loss She suffered from a constant cough with some production of dark brown sputum Additional history included five or six "spells" over the preceding three months characterized by vertigo and tachycardia of 10 to 15 minutes duration followed by somnolence for 4 to 5 hours There was some question of loss of consciousness at these times but this was not certain

On physical examination her blood pressure was 125/65 mm Hg and her body temperature was 37 2° C on admission She had a fine tremor of the hands and tongue Her lungs were clear to auscultation The apex impulse was palpable 1 cm lateral to the midclavicular line with a parasternal lift described A grade 3/6 systolic murmur was present at the base of the heart, with radiation to the carotid arteries and the apex This was considered to be a left ventricular outflow murmur Neither gallop rhythm nor diastolic murmur were auscultable

On the evening of the first hospital day her temperature rose to 39 4 C Blood cultures drawn on this day were later reported to be positive for a gram positive coccus A total of nine blood cultures were drawn during her first two h days and they were all positive for the sa nism which was further identified as

bovis

ts of the initial evaluation included f 11 5 g/dl white blood cell co with 72% neutrophils and telet count of 151 000/cu mm 10 6 second serum sodium potassium 4 3 mEq/L

vegetations on the left coronary and noncoronary valve cusps The aortic valve was replaced with a Bjork Shiley prosthesis At the completion of the surgery bleeding difficulties were encountered with hemodynamic instability Hemostasis was eventually achieved and she was treated with intravenous infusion of sodium nitroprusside because the systolic blood pressure had abruptly risen to 280 mm Hg Following this her systolic blood pressure fell transiently to 60 mm Hg before a more even control was achieved

In the early postoperative hours the patient had further bleeding problems from the surgical site necessitating a reoperation to secure hemostasis Her prothrombin time activated partial thromboplastin time and fibrin split products were now elevated and the plasma fibrinogen was low She was deeply comatose throughout the immediate postoperative period and she died the next day

Clinical discussion

DR SPITTELL To recapitulate what has been outlined in the case presentation the patient was an elderly woman who came here with a six month illness characterized by malaise fatigue anorexia weight loss and fever all fairly nonspecific symptoms She had a past medical history that included hypertension of 10 years duration and a heart murmur for 20 years You will note that prior to being seen here she had been managed as having had pneumonia but full documentation of this diagnosis was lacking Her laboratory studies included a sedimentation rate which was in a never never land of 40 mm/hr I would call your attention to her fasting blood glucose of 150 to 212 mg/dl and her blood pressure which ranged from 110/70 to 190/90 mm Hg in her past workups By the time she arrived here on November 30 she had had a 20 kilogram weight loss in the preceding six months Also noted were a couple of spells characterized by some vertigo and tachycardia followed by somnolence and possibly by loss of consciousness Other physical findings were as recorded and you will note that she had a grade 3/6 systolic murmur

The patient had fever during her initial day of hospitalization The growth of *Streptococcus bovis* from multiple blood cultures is worth spending a few minutes discussing *Streptococcus bovis* is a group D nonenterococcal streptococcus and there was a recent report by Klein and colleagues describing some unusual associations of infections by this particular organism These

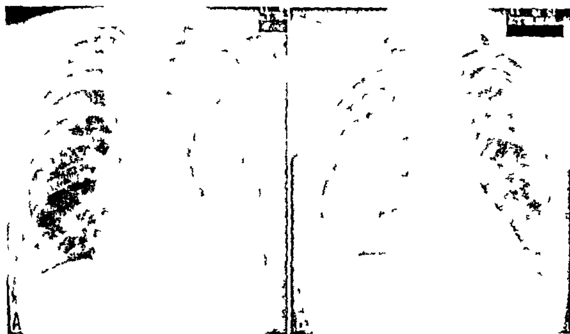

Fig 1 A Admission chest roentgenogram of November 30 19— showing a normal cardiac silhouette and pulmonary vascularity B Preoperative chest roentgenogram of December 15 19— showing increased pulmonary vascular markings and changes consistent with interstitial edema

blood creatinine 1 3 mg /dl fasting blood glucose 105 mg /dl serum glutamic oxaloacetic transaminase 27 U /L (normal 8 to 20 U /L) serum bilirubin 0 6 mg /dl total thyroxine 4 2 μg/100 ml (normal 5 to 13 5 μg/100 ml) syphilic serology nonreactive antinuclear antibody negative and serum iron 33 μg/dl (normal 60 to 180 μg/dl) with total iron binding capacity of 10% saturation (normal 18% to 50%) Serum albumin was slightly increased and gamma globulin was slightly decreased. The fungal and brucella blood cultures acid fast smears sputum cytology and urine cultures were all negative An intermediate tuberculin skin test showed 10 mm of induration An excretory urogram was normal and the admission chest roentgenogram (Fig 1A) showed some scattered fibrosis at the lung base and a normal sized cardiac silhouette An electrocardiogram (Fig 2) showed sinus tachycardia with minimal nonspecific ST T wave changes An ear nose and throat consultation was obtained regarding the vertigo spells and these were diagnosed as benign positional vertigo Two separate echocardiograms were done and were interpreted as negative for valvular vegetations though they did demonstrate evidence of calcium deposits on the aortic valve

After the initial positive blood culture results the patient began receiving intravenous aqueous penicillin G 20 million units every 24 hours plus streptomycin 500 mg every 12 hours. When the organism was further identified as *Streptococcus bovis* the antimicrobial therapy was changed to procaine penicillin 1.2 million units every 6 hours plus streptomycin 500 mg every 12 hours Despite this antibiotic regimen the patient continued to have malaise and a low grade daily fever of approximately 38° C

On the twelfth hospital day a 3/6 diastolic murmur of aortic insufficiency was heard for the first time Because the patient s condition continued to deteriorate aortic valve surgery was contemplated At that time two consecutive blood cultures were negative and the white blood cell count was 6 700/cu mm The prothrombin time activated partial thromboplastin time and the plasma fibrinogen were normal The electrocardiogram was unchanged and the chest roentgenogram (Fig 1B) now showed some interstitial edema The urinalysis showed 3+ red cells and hemoglobin in the supernatant

On December 19 1977 she went to surgery for aortic valve replacement At operation the aortic valve was described as calcified with extensive

Fig 4 *A* Gross appearance of pheochromocytoma attached to the right adrenal gland *(arrows)* *B* Photomicrograph of pheochromocytoma (Hematoxylin and eosin stain original magnification ×160)

murmur Subsequently as you note in the case presentation the patient s condition deteriorated and accordingly, on December 19 she underwent aortic valve replacement The chest roentgenogram (Fig *1B*) of December 15 four days before surgery showed changes of pulmonary venous congestion

At the completion of her surgery she had difficulties both with bleeding and with hemodynamic instability The surgeons eventually achieved hemostasis and managed her labile blood pressure with sodium nitroprusside However despite a second operation the patient never really responded and unfortunately succumbed the next day

We are faced then with a patient who had bacterial endocarditis and her aortic valve replaced perioperative labile hypertension and hemorrhagic diathesis and then was comatose following surgery I think one naturally must consider neurologic complications in this particular context and the paper published by Jones and co workers from this institution on the neurologic complications of bacterial endocarditis is worth summarizing briefly here Of 385 patients reviewed about 15% or 55 had a neurologic complication Of the total number of patients about 3% or 11 patients had a documented cerebral hemorrhage In these 11 cases the hemorrhage was intracerebral in eight and primarily subarachnoid in three The authors concluded that rupture of a mycotic aneurysm was the primary cause for the intracranial hemorrhage in their 11 patients This would mean that if all the people in their series who experienced cerebrovascular hemorrhage had mycotic aneurysms as the cause the incidence of ruptured intracranial mycotic aneurysm in bacterial endocarditis is about 3%

An advantage of having had the opportunity to review the patient s clinic and hospital records was the chance to read each and every note recorded The resident who did the admission workup on this patient made the following observations in his initial note *The patient was hypertensive for nine to 10 years she had had spells of vertigo with tachycardia for three months and she had had orthostatic spells for years* In the very last physician s note in the record at the time the patient died it was recorded that the blood pressure had been swinging widely from 250/160 to 30/0 mm Hg unrelated to any of our measures This to me was a very telling observation

I think that there are three diagnostic considerations in this woman in addition to her having had recent bacterial endocarditis The first is the possibility of an occult colon carcinoma associated with a *Streptococcus bovis* endocarditis The second consideration is rupture of a cerebral

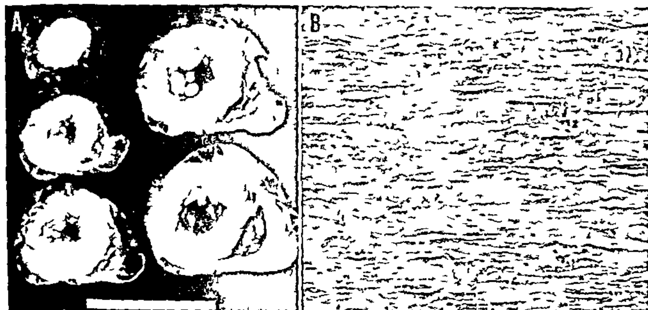

Fig 3 A Gross appearance of five consecutive slices of the transversely sectioned heart showing diffuse epicardial hemorrhage symmetrical left ventricular hypertrophy and absence of any old or recent myocardial infarction B Photomicrograph of subendocardium showing myofibrillar degeneration (Hematoxylin and eosin stain original magnification ×160)

investigators cultured the fecal flora of 278 subjects made up of seven different groups There were 105 control patients 63 patients with carcinoma of the colon 25 with inflammatory bowel disease 37 with other gastrointestinal disorders 12 with histories of previous carcinoma of the colon 15 patients with recently performed barium enemas and 21 patients with a noncolonic neoplasm In some patients cultures were taken from other sites on the body as well None of those samples from the axillary skin or the vagina showed positive cultures and only rarely (three of 45) could the organism be isolated from the throat or gingiva However on their fecal flora studies 56% of the 63 patients with cancer of the colon cultured *Streptococcus bovis* a significantly greater incidence of positive cultures for this particular organism than in any of the other patient groups examined The authors point out further that *Streptococcus bovis* may cause endocarditis almost as frequently as enterococci Although the association of carcinoma of the colon and infective endocarditis has been reported in only nine patients in at least four and possibly six of those nine patients the microorganism responsible for the endocarditis was *Streptococcus bovis* They conclude that it is prudent to evaluate patients with *Streptococcus bovis* endocarditis for possible carcinoma of the colon I think this is a very worthwhile piece of information to be brought to your attention

Proceeding further we see from the laboratory test results that our patient was anemic she had a modestly elevated blood creatinine and her fasting blood glucose was very slightly elevated (105 mg/dl) Her excretory urogram was normal as was her admission chest roentgenogram (Fig 14) Because the patient described episodes of vertigo the ear nose and throat service was asked to see her in consultation and after their examination they concluded that she had benign positional vertigo

The original cardiovascular consultant who saw this woman noted that she had been sick for six months she had a heart murmur she was anemic and she had had fever and weight loss He considered the possibility of bacterial endocarditis but he was concerned because in spite of her having had this illness for six months she did not have an aortic insufficiency murmur Two echocardiograms were done but did not really help in the diagnosis or in the identification of valvular vegetations Nonetheless after the results of the blood cultures were reported a therapeutic antibiotic regimen was instituted Then finally 12 days later the first observer noted a diastolic

made through workups of hypertension in eight patients as an incidental finding at laparotomy for an unrelated condition in four patients and because of the associated endocrinopathy in one patient Of the 41 patients with clinically unsuspected pheochromocytoma death was directly or indirectly related to the tumor and its complications in 30 patients—11 had intraoperative hypertensive or hypotensive crisis 11 had cardiac failure seven had cerebral hemorrhage and one had metastases[6]

Unexpected postanesthetic death and death during surgical procedures for unrelated conditions are well known complications of unsuspected pheochromocytoma[7,8] The surgical procedure may be a simple one such as the incision of an infected finger pulp or a breast biopsy[9] Pheochromocytoma is a true great mimic its clinical manifestations may be kaleidoscopic or minimal[4] Effective biochemical tests for the detection of pheochromocytoma are available[10] However a high index of suspicion is a prerequisite for the clinical diagnosis of pheochromocytoma If diagnosed it is curable in about 90% of patients but will eventually be lethal in almost all cases if untreated[4] Think of it confirm it find it and remove it[11] remains sound advice

mycotic aneurysm which of the possibilities that I entertained would statistically be the most likely The third consideration is a pheochromocytoma that had not been recognized While the latter is quite rare or considerably more rare than a mycotic aneurysm everything in this patient s story is compatible with that diagnosis This is because of the observations that were recorded in the last physician s note in the record of this patient and because of her spells her orthostatic symptoms and her past history of labile hyper tension

Dr Spittell s Clinical Diagnoses

1 Recent bacterial *(Streptococcus bovis)* endocarditis of the aortic valve

2 Recent aortic valve replacement

3 Perioperative cerebrovascular hemorrhage secondary to ruptured mycotic aneurysm To be ruled out are the possibilities of an unrecognized pheochromocytoma and coincidental carcinoma of the colon

Pathologic discussion

Dr Lie The autopsy was performed within 8 hours of death The immediate cause of death was indeed a cerebrovascular catastrophe The patient had a subdural hematoma over the right lateral convexity and middle fossa with compression of the right cerebral hemisphere and the rostral brainstem and uncal herniation There were also secondary hemorrhages in the midbrain and upper pontine tegmentum There were no cerebral aneurysms ruptured or unruptured

There was also hemorrhage into the anterior mediastinum (50 ml) the right pleural cavity (800 ml) and the left pleural cavity (100 ml) The heart was enlarged due to left ventricular hypertrophy weighing 680 g and there was generalized epicardial hemorrhage (Fig 3A) The aortotomy sutures were intact and the aortic valve prosthesis was securely seated With the exception of a focal 90% atherosclerotic luminal narrowing in the proximal third of the right coronary artery the extramural coronary arteries showed noncritical (< 75% luminal narrowing) atherosclerosis Scattered foci of fibrosis were present in the left ventricle Although there was no regional ischemic necrosis (myocardial infarction) foci of subendocardial myofibrillar degeneration[3] (contraction band necrosis) (Fig 3B) were widespread

Attached to the right adrenal gland was a large (8 by 6 5 by 5 cm) well circumscribed hemorrhagic tumor (Fig 4A) This tumor weighed 160 g and histologically was a pheochromocytoma (Fig 4B) A portion of the tumor was freshly frozen at the time of autopsy Subsequent chemical analyses showed that the tumor contained norepinephrine 21 8 μg/mg epinephrine 51 2 μg/mg and dopamine 0 3 μg/mg of the wet tissue

Thus we have an example of the *lethal complication of unsuspected pheochromocytoma* in a patient who had surgery for an unrelated condition namely *perioperative hypertensive crisis and hemorrhagic diathesis*

Dr Spittell Did the patient have any colonic lesion at all?

Dr Lie No nor was there any other neoplastic or endocrine lesion

Dr Olney After reviewing the patient s record in detail would you think Dr Spittell that the possibility of a pheochromocytoma was one that should have been considered by anyone caring for the patient preoperatively?

Dr Spittell We all get burned from time to time and I guess I have been burned by just about everything that burns One of the lessons I have learned is that when I have a patient who has hypertension it is always a good idea to consider the secondary forms of hypertension If I am going to send a hypertensive patient to surgery I would certainly like to have the results of urinary metanephrines

Dr Lie Pheochromocytoma is a tumor of neuroectodermal origin that arises from the chromaffin cells of the sympathoadrenal system Pheochromocytoma is not a common tumor its estimated frequency among the general population is approximately 1 per 200 000 per year In the 50 years since Dr Charles H Mayo reported the first successful surgical resection of a pheochromocytoma from this institution we now have in our autopsy files 54 patients with pheochromocytoma among the 40 078 consecutive autopsies performed in the period 1928 to 1977 This relatively high autopsy incidence of 0 13% would suggest that a significant number of these tumors may be clinically unsuspected This turned out to be precisely the case when we reviewed the records of these patients[4] The diagnosis of pheochromocytoma was not made clinically in 41 (76%) of the 54 patients Among the other 13 patients in whom the existence of a pheochromocytoma was known during life the diagnosis was

sociocultural mobility and changing life events is persuasive data from animal experiments directly and unmistakably links psychosocial disruptions to pathological changes in the cardiovascular system It is interesting that the prevalence of coronary artery disease and hypertension generally parallels the increasing complexity and ambiguity of social systems and social hierarchies whether we are speaking of animals or mankind Given the complexity of human interactions and psychology it is understandable that we should begin this discussion with the more well controlled experiments conducted in the less cognitively complex members of the animal kingdom

Work summarized by Mason[3] has shown that psychosocial stimuli can elicit either of two neuroendocrine responses One response involves arousal of the pituitary adrenal cortical system and the other that of the sympathetic adrenal medullary system Social interactions resulting in downward displacement in the social hierarchy lead to stimulation of the pituitary adrenal cortical system with mental depression decreased gonadotropin levels enhanced vagal activity, gluconeogenesis and pepsin production In contrast the sympathetic adrenal medullary system is called into play as agonistic or competitive behavior is invoked in an attempt to maintain status and prevent threatened loss of esteem and/or related objects of attachment

A variety of behavioral paradigms have been examined with regard to their influence upon the cardiovascular system in a variety of species Such animal experiments have included classical conditioning avoidance conditioning avoidance yoke procedure pre avoidance experience and psychosocial stress

Classical conditioning In Pavlovian or classical conditioning experiments a relatively neutral stimulus called a conditioned stimulus is immediately followed by another stimulus called the unconditioned stimulus After repeated pairing of conditioned stimulus followed by unconditioned stimulus the originally neutral stimulus comes to elicit a pronounced physiologic response Classically the conditioned stimulus has been a light or tone and the eliciting or unconditioned stimulus has been an aversive stimulus such as electrical shock. Yet it has been observed that when monkeys are given relatively long periods of habituation to restraining chairs with gradual shaping of responses and training sequences that minimize the ambiguity of stimulus cues the baseline he[...] rate during conditioning sessions can genera[...] kept near or even below the intrinsic rate[...] contrast when experimentally naive monkeys[...] given short periods of habituation with l[...] numbers of trials or training sequences that[...] not minimize ambiguity the pretrial base[...] heart rate is significantly in excess of the [...] value[4] In classical conditioning therefore, no[...] ty appears to be an important element. [...] noshvili and others[5] presented three rhesus m[...] keys with a number of stressful behavioral s[...] tions over a period of two years. The [...] prominent behavioral procedure was one in wh[...] a light signal followed by a shock was super[...] posed upon a bar press response for food. Du[...] the first four months on the training schedule, [...] investigators observed that blood pressure [...] creased from baseline levels but subsequen[...] sustained increase in blood pressure beg[...] develop When the animals developed ne[...] behavior the normal diurnal pattern in w[...] blood pressure heart rate and breathing [...] were greater during the day than at night be[...] altered and the authors observed that the ap[...] were out of phase

Avoidance conditioning In the avoidance [...] ditioning experiment the animal is traine[...] avoid stimulation by making a desig[...] response During signalled avoidance the [...] nism is warned that it must make a desig[...] response to avoid being shocked. Omaha Nebr

Curiously the concept that man s circumstances and emotions importantly influenced his circulation were long ago accepted by observant students of mankind Indeed few folklore notions have enjoyed as widespread and persistent popularity as those that ascribe sudden death to emotional shock Throughout history anecdotes appear about people dying suddenly in the throes of fear rage grief humilation or joy Yet with the ebb and flow of medical progress in the last century scientific measurement and laboratory observation assumed increasing importance in the evolution of medicine and such anecdotes held little sway in the scientific community Now history repeats itself and age old observations are being reexamined as a sizable body of evidence accumulates implicating psychosocial conflict emotions and behavioral patterns in the pathogenesis of coronary heart disease sudden death cardiac arrhythmias and systemic hypertension This interest has been heightened in investigations of coronary heart disease by the observation that the traditional risk factors fail to account for half of the cases of clinical coronary heart disease encountered on a worldwide basis

It is difficult to separate the role of behavior and environment from the accepted risk factors

Each risk factor is a composite of genetic environmental and behavioral components which can all be provoked enhanced or sustained by influences which are beyond simple metabolic or pathophysiologic explanations Thus in view of our incomplete knowledge of the pathogenesis of coronary heart disease and the likelihood that additional key factors are operating it is not surprising that preventive measures confined to a few factors have met with limited success to date The recent acceptance of Rosenman and Fried man s Type A behavior pattern as a statistically validated major risk factor is but one example of medical interest in psychosocial and behavioral influences In point of fact the results from most of the reported epidemiologic studies that generally incriminate the high fat intake of upper middle class Western man as the major cause of elevated serum cholesterol could just as well have been utilized to support the concept that rapid industrialization and the resultant socioeconomic stress were the responsible factors In addition to dietary intake and tobacco usage the lifestyle and society of Western industrialized man is distinctly different from that of populations manifesting a lower incidence of coronary heart disease While a complete understanding of how such influences participate in and are interrelated with other factors in the pathogenesis of cardiovascular disease remains the work of future investigation this work appears warranted on the basis of what is known and suspected

Psychosocial and behavioral influences in cardiovascular disease in animals

Whereas epidemiologic evidence linking coronary and hypertensive heart disease with prolonged emotional stress behavioral patterns

second is the brain stem hypothalamic system which is concerned with sex hunger, thirst and sleep drives It is at the level of cognitive integration however, where species differences become most apparent and this process involves the frontal association cortex and the parietal and temporal cross modal association areas termed the sociocultural brain Only in man do these structures attain such overwhelming proportions when compared to the rest of the brain

Nevertheless the strongest evidence for a potential or substantiated influence of psychosocial and behavioral factors in the pathogenesis of cardiovascular disease in man rests with manipulations of the social hierarchy and interactions of designated animal species Henry and Ely have demonstrated that fixed hypertension and myocardial hypertrophy progressive arteriosclerosis myocardial fibrosis and renal failure can be induced in socially deprived mice by subjecting them to social interaction Moreover Henry and Ely have shown that at least some of these changes were apparently mediated by an increase in the adrenal enzymes tyrosine hydroxylase and phenylethanolamine N methyltransferase The increases observed appeared to reflect a situation in which brief sympathetic discharges elicited by discontinuous emotional stimuli were transformed into sustained sympathetic arousal An important observation in addition to the impact of social manipulation is the fact that different genetic strains of mice have different levels of blood pressure and different potentials for synthesizing adrenal catecholamines They also have different temperaments responding differently in degree to the same social paradigm Thus the physiologic consequences of psychosocial provocation are largely engrafted upon a foundation of cultural and genetic predisposition

Von Holst in experiments with tree shrews introduced a subordinate animal to another male who was an experienced fighter After the subjugated animals were separated from the experienced fighters by a wire mesh but were allowed to continue to observe each other the subordinates would fall into comas within 2 to 16 days despite adequate food and drink and would die in uremia due to renal insufficiency Until the time of death the uremic subordinates manifested continuous piloerection as a manifestation of sustained sympathetic arousal Lapin and Cherkovich performed similar experiments in which they altered the social situation of dominant Hamadryas male baboons The male of this particular species adopts its females when they are still immature and develops an intense attachment for them When the dominant male was separated from his mate and another male was put into the female's cage in full view of the former consort, the displaced maled showed intense agitation After several months hypertension and other evidence of chronic cardiovascular disease developed in the original consort While some of the studies were aimed at developing experimental neuroses rather than deliberate cardiovascular disease the authors encountered a significant number of cases of hypertension coronary insufficiency and acute myocardial infarction

Ratcliffe[21] in studies at the Philadelphia Zoo observed that deaths in animals and birds from arteriosclerotic coronary heart disease increased from an incidence of less than 1% in 1949 to more than 10% in 1968 Diet and mean age at death were no different but he did note that in 1949 the zoo began an attempt to assemble family groups This contrived social grouping resulted in conflicts breeding failures and abnormal behavior within the family groups" He eventually concluded that the increase in coronary heart disease resulted from behavioral responses in these social situations He then did an experimental follow up studying the psychological responses of swine to separations occurring after the primary social bonds of grouped animals had been formed At the end of a year the separated animals showed a significantly greater incidence, extent and severity of coronary atherosclerosis Whereas grouped and paired swine responded to human visitors with friendly grunts and squeals for a handout those swine that had been separated especially the normally friendly females failed to respond to visitors and even refused offers of added corn

Weber and Vander Walt produced cardiomyopathy in New Zealand white rabbits by alternately housing them singly and then crowding them again In the course of ten months 30 of the animals had expired with ten dying during the first week ten more during the first month and the rest at intervals during the succeeding months In those dying within a few days, severe myocardial necrosis was observed in the subendocardium and myocardium Those that survived longer developed foci of myocardial fibrosis and

the animal fails to meet the scheduled requirement both the animal and its yoked partner receive shocks Thus both animals always receive the same number and temporal pattern of shocks but only the avoidance animal has control over whether shock will occur In such experiments Corley and colleagues[12] observed that five of six "yoked" monkeys developed physical deterioration and severe bradycardia with ventricular arrest but no significant myocardial necrosis In contrast, the avoidance monkeys developed electrocardiographic abnormalities and myocardial degenerative lesions Such unsignalled avoidance can activate the sympathetic autonomic nervous system yielding a direct action of norepinephrine upon beta receptors in the myocardium which results in myocardial necrosis Richter[3] demonstrated the adverse consequences of yoked helplessness when he demonstrated that rats developed fatal vagally mediated bradycardia after being subjected to severe unavoidable water stress Interestingly Schneider observed that among patients who had a past myocardial infarction those with the greatest tendency to bradycardia in response to startle also had the poorest prognosis In Corley and associates experiments[2] the key difference leading to divergent pathologies was that the animals in the avoid condition had control over whether they received shock but the yoked animals did not Also the occurrence of shock was somewhat predictable in the avoid but unpredictable in the yoked condition.

Preavoidance experience Animals subjected to repeated sessions of avoidance conditioning eventually had changes in their baseline cardiovascular physiology during the period immediately preceding the session Such prior experience can influence the organism s behavioral physiological and biochemical responses Anderson and Tosheff[5] studied the cardiovascular responses of dogs during daily sessions consisting of a one hour anticipation period followed by an hour of unsignalled shock avoidance When the animals were placed in a harness for the hour immediately preceding the daily sessions of unsignalled avoidance the animals manifested a progressive decrease in heart rate and cardiac output accompanied by a progressive increase in total peripheral resistance Studies by Adams and co workers using cat fight confrontations with glass partitioned separation demonstrated that shortly before the episodes of fighting began both heart rate and cardiac output decreased while total peripheral resistance increased These studies suggest that during an orienting reflex total peripheral resistance increases The orienting reflex response is hemodynamically similar to the diving reflex and has been elicited by electrical stimulation of the brain stem in rats[1] This reflex pattern has been suggested as one mechanism for sudden death as manifested in the experiments of Corley and associates[2] using monkeys and Richter[3] using rats Such studies have resulted in the concept of learned helplessness According to the learned helplessness hypothesis animals exposed to a stressor they cannot control may learn that their behavior cannot control the environment The biochemical explanation for this behavior appears to involve depletion of brain norepinephrine Glazer and co workers[17] found that depletion of monoamines by a single injection of tetrabenazine produced a depressed response to escape in rats when the avoidance escape response involved a relatively high degree of motor activity but not when a minimum of motor activity was required These investigators also observed that by decreasing the stress induced depletion of monoamines by the use of an MAO inhibitor they could protect the animals from the effects of inescapable shock Thus the MAO inhibitor reduced the learned helplessness produced by unavoidable shocks. Studies of cardiac somatic coupling by Obrist and colleagues[8] have indicated that vagally mediated reflexive bradycardia occurs in sympathetically aroused animals when these animals inhibit their somatic activity The vagally mediated cardiac component of the baroreceptor reflex is sufficiently strong to override the concomitant sympathetic activation of the heart[19]

Psychosocial stress The constellation of influences in cardiovascular disease most clearly approximating those seen in man occur during experiments involving manipulation of the social hierarchy of animal colonies So far we have discussed a variety of experimental methods resulting in diverse neuroendocrine responses which may be elicited singularly sequentially or in concert These responses are mediated on the effective integrative level through two major pathways The first is the limbic striatal system which is involved in the social emotional and selfpreservation behavior of animal species The

costeroid levels which were originally high showed progressive decline while epinephrine and norepinephrine levels showed progressive upward trends This suggests that the rat altered its response to the experience Early immobilization might be regarded as a threat against which the animal was helpless had no coping defenses and a perception of loss of control However with repetition although the event was equally noxious it was perceived as having a predictable outcome Thus there are three major indications from experimental data

1 Animal studies demonstrate that as a result of emotional arousal purely cognitive processes can lead to neuroendocrine changes of the adrenal medullary and/or adrenocortical systems and that dependent upon the environmental situation and coping mechanisms available such responses may be elicited singularly sequentially, or in concert

2 Different psychosocial and physiological changes develop according to the emotion predominantly concerned Anger challenge and fear are associated with the fight or flight response and sympathetic adrenal medullary activation with the familiar chain of physiological changes

3 Depression is found in situations fraught with loss of control such as feelings of helplessness and subordination In contrast it involves activation of the pituitary adrenocortical system and depression of gonadotropins

The clinical relevance of these observations is supported by Bourne s studies[29] of men during combat in Vietnam and by Katz and colleagues studies[30] of women awaiting biopsy reports of a lump in the breast Both studies showed that feelings of social acceptance and high personal worth which commonly accompany effective psychiatric defenses are associated with decreased activity of the pituitary adrenocortical system Carroll s[31] work complemented these studies and demonstrated that primary depression accompanied by lack of self worth was associated with the reverse response of increased activation of the adrenal cortex

In addition there is an increasing amount of experimental evidence linking the central nervous system to lipid metabolism and atherosclerosis Chronic stimulation of the ventral medial nucleus of the hypothalamus of cholesterol fed rabbits significantly elevated plasma cholesterol levels[3] and exposure to a continuous auditory stimulus of white noise induced enhanced alimentary hyperlipemia in rats and rabbits[34] An invol ment of adrenal gland activity in the lipem response to auditory stimuli has been noted the finding that such stimuli induce a mark increase in adrenocortical steroid secretion, a this activity may persist for some weeks af exposure to auditory stimuli On the other ha removal of the adrenal glands and the hypophy did not abolish the milieu induced postprand hyperlipemia of fat fed rats[3] However an el trolytic lesion placed in the anterior hypotha mus does prevent the milieu induced postpr dial hyperlipemia otherwise observed in th animals Hypercholesterolemia can be induced rats by bilateral injury of the ventral med nuclei of the fornices and the medial portion the lateral hypothalamic nuclei, but cannot ascribed to any change in function of the thyr adrenals testes or pituitary that might have b induced by the hypothalamic lesion nor can it ascribed to any induced derangement of p creatic discharge of insulin[35]

Studies of spontaneous vascular lesions in a mals yield important information which is use in assessing the role of various risk factors in process of atherosclerosis Such animal stu provide baseline data for comparison with exp mentally induced arterial lesions in that spe and also provide a panorama of the types lesions which may occur in the *animal* kingd They yield insight into the pathogenesis of art al disease in particular species provide infor tion regarding the types of *lesions* occur throughout the animal kingdom and permit mulation of hypotheses concerning arterial ease in general

compensatory myocardial hypertrophy in the fibers adjacent to the fibrotic areas

The previous discussion provides ample evidence that environmental novelty and/or adversity particularly when sustained is capable of eliciting physiologic responses which when unabated may lead to pathologic consequences In addition psychosocial interactions are powerful and important influences in eliciting such responses Henry and Ely[9] have pointed out however that social stimuli do not act directly on the individual Rather perception of the social environment as mediated by personality role and status variables arouses emotions which induce physiologic responses An important aspect of such discussions is that in addition to the impact of social manipulation different genetic strains have different levels of blood pressure and different potentials for synthesizing adrenal catecholamines They also have different temperaments responding differently in degree to the same social paradigm Thus the physiologic consequences of psychosocial provocation are largely engrafted upon a foundation of cultural and genetic predisposition and are effected principally through cognitive mechanisms

It is known that stress such as cold heat fasting or exercise fails to elicit typical neuroendocrine responses of either the sympathetic adrenal medullary or pituitary adrenocortical systems if emotional arousal is avoided[26] This has been illustrated in early studies of the effects of three day fasting on two of eight monkeys housed in the same room The deprived monkeys often vocalized in apparent protest when the caretaker handed food pellets to the others The elevation of 17 hydroxycorticosteroids on the first day of the fast suggested that psychological as well as nutritional factors might be at work since the fasting monkeys were exposed to all the sights sounds and stimuli associated with routine feedings and the presence of the nonfasting monkeys If novelty and uncertainty were carefully minimized by allowing the monkeys time to adapt to experimental conditions outside stimuli eliminated by soundproofing and discomfort minimized by giving the monkeys non nourishing fruit flavored pellets no change in steroid levels occurred during fasting periods These sorts of studies strongly suggest that rather than social stimuli acting directly on an individual personal assessment of the social environment uniquely refracted through one s self image and value perceptions arouses emotions which produce physiologic responses

Within the society whether animal or man a hierarchy exists and approved behavior must be exercised It is not only man who responds to a life situation by how it affects him personally a monkey whose parents are dominant members of a troop is likely to attempt a dominant role Socially deprived and formerly isolated animals that give vent to their irritation at the expense of an infant or a more dominant group member receive short shrift from the infant s parents or an offended social superior A well adapted subordinate of any species knows he must wait his turn patiently and show respect for those higher in social rank If a psychosocial stimulus is inhibited at higher levels by interaction with coping patterns it will be perceived as irrevelant within the frame of reference If perceived as relevant however arousal is triggered and limbic system components respond initiating further trains of responses

Studying dominant and subordinate males in mouse colonies Ely and Henry verified that change of status is associated with altered neuroendocrine patterns. They demonstrated that the enzyme tyrosine hydroxylase which is under sympathetic control and the rate limiting enzyme in the synthesis of norepinephrine rose more markedly in dominant mice than in subordinates as struggle for status in the newly formed social hierarchy progressed Phenylethanolamine N methyltransferase which converts norepinephrine to epinephrine not only increased in dominant animals but continued to rise while falling in subordinates as they adapted to a loss of status Once the mice adapted to each other in the colonies these changes were no longer seen during later stages of interaction as the social hierarchy stablized On the other hand during the unstable phase of the social hierarchy subordinates demonstrated marked increases in plasma cortisol levels which returned to normal levels when the social hierarchy became stable and established Whereas challenge and anxiety elicit sympathetic and adrenal medullary responses loss of control and depression are associated predominatly with corticosteroid responses Studies indicate that a gradual shift occurs in the nature of a rat s response to immobilization when taped to a laboratory bench With repeated experience corti

per capita consumption of alcohol Some of the recognized factors contributing to the psycholog ical distress in this society were (1) the perceived national urgency of putting a man on the moon by the end of 1969 (2) the great national and international visibility of the Center in which a dramatic failure would have adverse occupational consequences (3) the problems of interpreting and coordinating the work of approximately 300 different major industrial contractors particular ly for administrators and managerial personnel engaged in interorganization liaison (4) the pro gressive decline in budget and employment and (5) the resultant threat of loss of employment identity and income from lack of demand for overspecialized and highly trained skills inappro priate to the common marketplace In short the project demanded an ever increasing if not fren zied pace of production with the ultimate reward of nearly inevitable dismissal financial loss and loss of professional identity

There were findings of an unusually high per cent of abnormal resting electrocardiograms [30] In addition there was a remarkable incidence of psychoneuroticism anxiety and depression with in the population [31] Postmortem myocardial his tologic features of victims of sudden death dem onstrated the existence of hyperfunctional anomalous contraction bands This same histo logic picture of hyperfunctional necrosis can be quickly induced in the hearts of animals by the administration of boluses of catecholamines [32] The abilities of catecholamines to facilitate rhythm disturbances increase myocardial oxygen demand augment vascular reactivity and mobil ize free fatty acids are well established facts The results of animal experimentation have demon strated the protective effect of pretreatment with beta blockade and recent studies suggest that beta blocker therapy has a beneficial impact upon the incidence of coronary death in some coun tries Many years ago Raab maintained that corticosteroid administration potentiated and augmented the myocardial degenerative in fluences of catecholamine administration in ani mals Animal experimentation strongly suggests that the combination of heightened sympathetic arousal followed by a complete sense of hopeless ness and helplessness is a particularly lethal combination for the development of sudden death [35] In a national sense the KSC workers were struggling winners who finally did achieve in putting a man on the moon In a personal and professional sense the inevitable dismissal and loss of professional and financial security resulted whether they succeeded or failed at their mission This placed many of them in a situation of being ultimate losers in a joyless struggle For most highly specialized aerospace personnel the Kennedy Space Center experience was an overall Pyrrhic victory on a personal level. The combined factors of arousal struggle loss and helplessness are clearly evident in retrospect in this study and are hauntingly reminiscent of a multitude of experiments employing yoked and restrained animals

A large number of experimental animal studies have strongly implicated psychological stress in the precipitation of arrhythmias and sudden death Several reports have recently appeared in the literature documenting the effects of psychological stress in lowering the threshhold for ventricular fibrillation and sudden death both in animals and in man [3, 34, 37] The combination of arousal with enforced helplessness and extreme conflicting stimulation has been demonstrated by Gelhorn [3] to result in breakdown of the reciprocity between the fight or flight reaction and the playing dead reaction Under overwhelming stress both systems become active simultaneously or in rapid alternation with each other This constitutes the neurophysiologic basis for the behavioral disorganization typically exhibited by animals under extreme stress the dog that struggles crouches trembles moves about aimlessly barks whines salivates urinates, defecates pants piloerects and sometimes momentarily dozes All these activities indicate simultaneous or rapidly alternating sympathetic parasympathetic activation

Although it is difficult to conduct controlled human studies comparable to those readily obtained in animals electrocardiographic monitoring during a variety of psychologically stressful tasks in humans has documented significant and potentially fatal rhythm disturbances in direct association with episodes of emotional stress [9] Thus it appears that continuous ECG monitoring can provide previously unavailable physiologic data on the process of dying Advancing technology is beginning to illuminate pathophysiologic processes which may offer guidance to the factors which can lead to lethal consequences and techniques suitable for their control. Of

uggests that mechanical stress may be an impor ant operative factor Stout and colleagues[37] have lso demonstrated that chronic low intensity lectric shock is associated with an increased roliferation of aortic fibrous plaques in minia ure pigs While many investigators feel that entral plaque necrosis in human atherosclerosis s due to accumulation of lipids within the cells of he plaque atherosclerotic plaques of giant nteaters and aardvarks manifest central plaque ecrosis before lipid accumulation[38] Moreover requent areas of focal plaque necrosis apparently nvolving smooth muscles were found within brous plaques in a number of species These reas of focal necrosis were also present within brous plaques of experimental pigs receiving hronic electric shock

It is apparent from the foregoing discussion hat atherosclerosis presents manifold counte iances but is relatively commonplace in the animal kingdom However captive birds seem to show a higher incidence of atherosclerosis per iaps because of their higher blood pressures and erum cholesterol levels

Regarding the influence of serum lipids in the therosclerotic process it has been shown that here is a bidirectional transfer of cholesterol in normal aorta with equal movement of lipid in and out of the endothelium However when the inti na becomes abnormal lipid movement into the rterial wall predominates Superimposed upon he ubiquitous atherosclerotic lesion are species pecific factors It seems that attributes of a pecies are a preponderant factor in the develop nent of atherosclerosis It is certain that being a ird is more important than the type of diet onsumed since graminivorous birds have far more atherosclerosis than do graminivorous ani nals and so on A unique peculiarity of human therosclerosis is the sequela of thrombus forma ion and this implies that platelet aggregation lays a significant role in the ischemic sequelae It s against this background of animal and experi nental information that the role of psychosocial actors stress and behavior in the pathogenesis of ontemporary clinical cardiovascular disease will e viewed and discussed

linical cardiovascular disease

We may look at cardiovascular disease in terms f distinct entities such as hypertension coronary eart disease and sudden death but we must ecognize that they seldom stand in isolation and that overlapping relationships exist The clinical observations linking psychosocial environmental and behavioral factors with atherosclerotic and hypertensive cardiovascular disease arrhythmo- genesis and sudden death are too extensive to permit a comprehensive discussion within the scope of this review and the reader is referred to a number of reviews in the literature[3] [4] We will briefly highlight some observations regarding psy chosocial and behavioral factors as they relate to sudden death coronary heart disease and hyper tension These will then be synthesized into a composite of hypothetical mechanisms that may interrelate the accepted risk factors

Sudden death

Few folklore notions have enjoyed as wide spread and persistent popularity as those that ascribe sudden death to emotional shock Far back in recorded history people are described as dying during emotional upheaval Almost 2 000 years ago Celsus[5] described that emotional states could influence the heart William Har vey[5] reaffirmed the observation in 1628 by stat ing that fear and every affection of the mind that is attended by either pain or pleasure hope or fear is the cause of an agitation whose influence extends to the heart In more recent times such influences have been causally implied by Hunt er s prediction of the circumstances of his death and by Cannon s observations on voodoo death Even Osler[4] commented on the behavioral aspects of sudden coronary death in his straight forward and simple description of the coronary prone individual as a keen and ambitious man the indicator of whose engines is set at full speed ahead However with the advent of scientific medicine in the late nineteenth century such observations fell into disrepute as scientific and traditional medical approaches dictated that the cause of death should be established at the necropsy table and in the laboratory

As an epidemiologic phenomenon the inci dence of sudden death at the Kennedy Space Center during the mid 1960 s strongly suggested the influence of psychosocial and behavioral fac tors Although traditional risk factors were not remarkable the sudden death rate among men at the Kennedy Space Center (KSC) was nearly 50% higher than that of age and sex matched control groups (Warheit and Eliot unpublished manu script) The divorce rate was three out of four marriages and this microcosm led the nation in

members of the cohort. The diets of all the chimpanzees contained 10% of total calories as fat. Both animals manifesting predominant coronary and cerebral atherosclerosis had adjusted poorly to captivity, showing neurotic traits such as stereotyped posturing, hoarding of food and other objects, and poor socialization with peer animals in the colony.

While dietary fat intake appears to be statistically important, the documented observations that dietary cholesterol is limited in absorption and that most cholesterol is manufactured in the liver suggests that other factors might be importantly involved. It is curious that Friedman and colleagues studies[43] of accountants demonstrated that their highest serum cholesterol levels consistently occurred during periods of severe occupational and emotional stress. Conversely, minimal values occurred during periods of minimal stress despite unchanged levels of dietary fat intake. While fat feeding rabbits to produce atherosclerosis has been carried out as a reliable animal model for the last 60 years, Nerem[44] reports that if the animals are fondled or given daily doses of diazepam, the extent of atherosclerosis is significantly reduced despite comparable levels of attained hypercholesterolemia. Thus, the association between dietary intake of fat and atherosclerosis is an incomplete association. One should recognize that the dietary hypothesis arose primarily from studies involving prosperous industrialized competitive societies and restrained, fat fed, socially isolated animal models.

A third risk factor is cigarette smoking, and there is little question that carbon monoxide inhalation and nicotine exposure have definite physiologic consequences. Nicotine is a stimulator of both sympathetic and parasympathetic ganglia and increases the arterial epinephrine concentrations in man. Nicotine also induces ADH secretion, liberates catecholamines from the heart, increases heart rate and cardiac output, lowers the threshold for ventricular fibrillation and causes peripheral vessel constriction. Nicotine increases free fatty acids in serum through its catecholamine release and usually promotes the development of atherosclerotic lesions in fat fed animals.[45] Necrosis and calcification of the medial layers of aorta were often seen in these animals and this might be explained by an effect of catecholamines since their administration to animals has a similar effect. The effect, if any, of smoking on blood coagulation and the function of platelets is probably related to an action of nicotine since carbon monoxide exposure does seem to have any effect. Carbon monoxide does induce arterial hypoxia which accelerates atherosclerosis in cholesterol fed rabbits.[46] There is no qualitative difference between lesions in animals exposed to carbon monoxide and animals exposed to hypoxia.

However, in addition to powerful physiologic effects, it is obvious that smoking constitutes a cultural and behavioral phenomenon as well. In Keys' seven country study,[47] the findings were that nonsmokers consistently differed from smokers in being relatively heavier and fatter and tended to have higher blood pressures, except in Japan where there was no consistent difference. Light smokers tended to have lower serum cholesterol values than their fellows in the same sample, but otherwise serum cholesterol showed little or no relationship to smoking habits in most areas. Exceptions were in Slovonia, Montenegro, Crete, and Corfu where nonsmokers tended to have higher cholesterol values and in Velika Krsna, Yugoslavia, where the opposite tendency prevailed. In general, the higher blood pressures in the nonsmokers could not be explained by the excess of obese men in this group. Indeed, the high prevalence of smoking in Corfu and Japan correlated negatively with electrocardiographic findings of coronary heart disease, a statistical anomaly at variance with studies of United States populations.

There are obvious health reasons for discouraging the smoking habit, yet it appears obvious that genetic and sociocultural behaviors might participate in modifying results in the etiologic relationship between cigarette smoking and atherosclerotic coronary heart disease. In addition to its identity as a risk factor, cigarette smoking is a sociocultural behavior which in some societies and cultures is negatively or insignificantly correlated with atherosclerosis. These comments are not intended to minimize the health consequences of the smoking habit but merely to point out that despite the powerful physiologic effects of tobacco smoke, there is not an immutable relationship with coronary heart disease in all populations, cultures and societies. In studying this risk factor's relationship to coronary atherosclerosis, the sociocultural and motivational aspects of the habit should be examined in addition to its prevalence.

An additional link to be considered in the

perhaps equal importance is the fact that animal studies have taught us that the same experimental environments may produce different results in different species dependent upon genetic experiential and cognitive functions. Different results may also be obtained by altering time frames or options within animals of the same species. Such findings indicate that the impact and countenance of a psychosocial stimulus in the human as in various animal species, is related to individual cognitive functions circumstantial novelty and psychological defenses. The likelihood of an event eliciting an adverse physiologic response depends also upon a complex amalgam of factors including genetic predisposition early social experience and a lifelong process of conditioning and cultural factors.

Therefore, we believe that ambulatory monitoring as a measure of physiologic response should be correlated with aspects of cognitive behavior. The influence of psychosocial and behavioral factors is becoming increasingly well substantiated in the clinical areas of arrhythmogenesis and sudden death. A variety of physiologic mechanisms contributing to these clinical phenomena are being discovered and examined. The aspects of cognitive integration eliciting such responses remain an important frontier for further investigation.

Atherosclerotic coronary heart disease

While the link between observed environmental provocation and physiologic response is relatively immediate and direct in studies of sudden death the role of psychosocial and behavioral factors in coronary heart disease is far more complex and elusive yet these appear to be culpable. Considering the slow evolution of clinical coronary heart disease and our incomplete knowledge of the pathophysiology of atherosclerosis and the mechanisms of its sequelae one can hardly expect more proof than guilt by association. Because we really do not fully understand the mechanism whereby any heretofore commonly accepted coronary risk factor effects arterial damage we still have to determine the intrinsic biophysical metabolic and neurochemical processes which over prolonged periods of time eventuate in the onset of clinical coronary heart disease. When such fundamental mechanisms are understood it should not be too difficult to track down the precise cardiopathic pathways which might be fostered by psychosocial and behavioral factors.

At the present state of our understanding it appears that the atherosclerotic process involves injury and proliferation of intimal smooth cells with subsequent alteration in permeability and/or metabolism and tends to occur at bifurcating or originating sites of vessel branches. With the progressive insudation of lipid material hemodynamic impairment to flow eventually results. The site of lesion formation suggests that hydrodynamic stress and shear forces participate in the process. This also suggests that the higher and more frequent the kinetic energy trauma to the circulation at these points of turbulence the more rapid the evolution of the lesion. While these findings are consistent with hypertension as a risk factor it is obvious that additional factors are operative. Those individuals possessing the $C3^F$ gene in essential hypertension have a coronary risk rate nearly seven times higher than those who are $C3^F$ negative. Furthermore epidemiologic studies in Japan suggest that in some populations the incidence of hypertension may be remarkably high without a concomitant increase in atherosclerotic findings. Thus the association is incomplete but it is generally accepted that elevated blood pressure and increased shearing forces constitute an aggravating cause in the development of atherosclerosis. The behavioral aspects of hypertension will be discussed later.

A second factor having obvious face validity is that enhanced lipid availability is an integral part of the atherosclerotic process. Here also psychosocial and behavioral factors appear to be involved. Dietary fat intake has long been incriminated as the major factor in this process notably through some epidemiologic studies and by fat feeding various animal species. Nevertheless several observations suggest that dietary fat intake is not exclusively related to the process. Andrus and associates published one attempt to induce atherosclerosis in chimpanzees through high fat high cholesterol feeding. In that study it was interesting that although there were more aortic fatty streaks in the experimental animals than in controls this difference was less pronounced in the epicardial coronary arteries and there was no difference in the cerebral arteries. Stout and Bohorquez[7] found epicardial and cerebral atherosclerosis in two of their chimpanzees which was significantly advanced over that found in other

2 Serum lipids whether available through dietary substrate or mobilized by central nervous system factors enhance and foster smooth muscle cell proliferation and become incorporated within the proliferative and necrotic lesion

3 The smoking habit through its nicotine effects on catecholamine excretion and consequent physiologic effects in collaboration with the effects of carbon monoxide upon vascular permeability tends to promote mechanisms contributing to atherogenesis

4 Platelet mobilization and aggregation directed toward areas of endothelial trauma release a platelet derived growth factor and the vasospastic agent thromboxane A_2 contributing to smooth cell proliferation in combination with vasoactive constriction

Many of the incriminated mechanisms appear to work through or are activated by catecholamines in concert with hyperlipemia Catecholamines are probably the most important factors promoting lipid mobilization They are effective in mobilizing lipid from adipose tissue both by their liberation from non adrenergic nerve terminals in adipose tissue and by their secretion from the adrenal medulla into the blood The free fatty acids not stored or utilized in the production of energy are eventually taken up by the adipose tissues or by the liver Free fatty acids taken up by the liver are formed into triglycerides and are secreted as components of very low density lipoproteins The rate at which the liver secretes very low density lipoproteins is determined partly by the rate it synthesizes free fatty acids from carbohydrates and partly by the rate it receives free fatty acids in the blood In the fasting state the secretion of very low density lipoproteins by the liver is determined principally by the levels of free fatty acids in the blood These levels in turn are determined principally by the effects of catecholamines on adipose tissue and by the rates of energy production Catecholamines promote platelet adhesiveness and aggregation promote arrhythmias and lower the threshold to arrhythmia generation and increase secretion of glucagon thyroxin calcitonin parathormone renin erythropoietin and gastrin while diminishing insulin secretion Glucocorticoids convert protein into carbohydrate and fat have a minor antagonistic effect on insulin promote the development of diabetes foster hyperlipidemia and hypercholesterolemia enhance water diuresis diminish circulating lymphocytes reduce leukocytosis and polycythemia increase platelet counts with an enhancement of clotting tendencies lower the electrical excitation threshold of the brain increase gastric acidity and pepsin production block growth hormone secretion decrease calcium absorption enhance angiotensinogen production sensitize arterioles to the pressor effect of catecholamines and decrease the inflammatory response Accelerated atherosclerosis is one of the main causes of death in Cushing's syndrome whereas the sequelae of pheochromocytoma include hypertensive crises myocardial infarction with or without coronary disease arrhythmias and catecholamine myocarditis Both of these endocrine excesses have been demonstrated to occur in reactions to various psychosocial circumstances mediated by cognitive perceptions

Type A behavior

The term Type A behavior was coined by Friedman and Rosenman almost two decades ago, but the association between a typical behavioral pattern and victims of coronary heart disease had been previously recognized by others including Osler's succinct description at the turn of the century A recent conference sponsored by the National Heart Lung and Blood Institute appraised the role of behavior as a predictor of potential coronary heart disease The review panel convened by this Institute accepted the available body of scientific evidence as demonstrating that Type A behavior as defined by the structured interview used in the Western Collaborative Group Study, the Jenkins Activity Survey and the Framingham Type A behavioral scale was associated with an increased risk of clinically apparent coronary heart disease in middle aged U S citizens The risk was found to be beyond that imposed by age elevated systolic blood pressure serum cholesterol, or cigarette smoking and appeared to be of at least the same order of magnitude as the relative risks associated with the latter three of these factors

Type A behavior was described as an aroused state superimposed on a complex underlying substrate of interrelated factors Metaphorically it can be viewed as an iceberg with a small portion apparent above the surface Unfortunately situational or environmental determinants, individual perceptive or cognitive differences and other psy

atherosclerotic chain of events is the role of platelets and thrombosis This phenomenon appears to be distinctive for atherogenic sequelae in man as compared to the rest of the animal kingdom If smooth muscle cell proliferation lipid accumulation and thrombosis are parts of the atherosclerotic mosaic clotting and platelet function must be suspected as potentially culpable agents in the process It has been suggested that repeated or chronic endothelial cell loss may be the principal event leading to atherosclerosis[66] Furthermore the intimal lesions that occur in homocysteine induced or mechanically induced arteriosclerosis can be prevented by pharmacologic agents that interrupt platelet consumption or by inducing a thrombocytopenia with an anti serum of platelets[67] The endothelium normally regulates the entrance of low density lipoproteins (LDL) the principal cholesterol carrying lipoprotein of the plasma into the artery wall Low density lipoproteins also support smooth muscle proliferation in cell culture Although LDLs may mitogenic they more probably provide nutrients necessary for cell proliferation in terms of new membrane formation Human fibroblasts contain specific receptor sites for LDL and arterial smooth muscle cells are thought to have similar receptors that play a role in controlling the intracellular synthesis of cholesterol Recent investigations demonstrate that platelet alpha granules contain platelet derived growth factor (PDGF) a potent stimulator of smooth muscle cell proliferation[6] Since increased platelet activity in vitro has been reported in patients with familial hypercholesterolemia it is necessary to determine whether the decreased survival is a direct effect of increased cholesterol or lipoproteins upon the platelets or is a manifestation of increased platelet consumption by exposed subendothelial surfaces

Ross and Harker[66] performed matched cross over platelet survival experiments in normal lipidemic and hyperlipidemic monkeys and demonstrated that platelets from hyperlipidemic monkeys survived normally after infusion into normal lipidemic animals In contrast platelets from normal lipidemic animals infused into hyperlipidemic animals had a decreased survival time comparable with that of autologous platelets While such data do not rule out the possibility of a rapidly occurring lipid mediated effect on the membranes of transfused platelets the reduction in platelet survival is most consistent with increased platelet consumption on exposed subendothelial surfaces as observed in the desquamation associated with homocystinemia and in prostheses such as artificial valves or vessels Platelet derived growth factor (PDGF) in contrast to the situation with other polypeptide hormones is distinctive in that the predominant delivery system for PDGF is the platelet rather than the plasma PDGF is primarily carried through the circulation in the alpha granules of the platelet and while it is in this cryptic state it cannot stimulate cell replication Since platelets have an affinity for injured sites they provide a remarkably specific delivery system for this polypeptide hormone which initiates the replication of arterial smooth muscle cells in vitro and may do so in vivo

As a further support of the role of platelets in atherosclerosis it should be remembered that pigs with von Willebrand s disease have a defect in platelet adhesion Bowie and associates showed that such animals failed to develop the athero-sclerotic lesions that occur in control animals made hypercholesterolemic by a fatty diet. Thus a suspected fundamental response following some form of injury to the endothelium may be platelet mediated intimal smooth muscle proliferation In addition when vascular damage leads to platelet deposition in the endothelial wall liberation of the vasoconstrictor thromboxane A_2 occurs tending to propagate the platelet aggregation process and perhaps collaborating in the development of coronary spasm [71] Enzymatic formation of prostacycline is specifically inhibited in vitro by lipid peroxide such as 15 hydroperoxyarachidonic acid and inhibition of the formation of this thrombolytic agent by lipid peroxides may provide an explanation for the development of some thrombotic episodes A variety of studies have demonstrated the ability of catecholamines to enhance platelet stickiness and aggregation while other studies have demonstrated increased platelet aggregation and consumption under a variety of situations both emotional and physical broadly referred to as stress [73]

To summarize what is known and highly suspected about the hypothesized roles of the various risk factors in the atherogenic process

1 Hypertension increases local vascular trauma turbulence with its greatest hydrodynamic impact at branching sites of vascular origin and serves as an instrument for inducing mechanical trauma

might be called competitive arousal struggle for dominance and the expected psychomotor consequences of the fight or flight mechanism With regard to the previously mentioned animal studies concerning alterations in the environment it seems reasonable to suspect that environmental stress and sociocultural factors importantly influence the type of behavior observed Industrialized western societies have in common a depersonalized complexity and reward system for the effective competitor In general these societies tend to reward those who are time urgent and aggressive Thus in some ways there is a curious resemblance between Henry and Ely s studies of an agonistic society in mice and contemporary industrialized societies

We would contend that a social structure which positively reinforces competition aggression and time urgent performance would result in a perpetual dynamic struggle for status and dominance so characteristic of the Type A psychomotor behavioral pattern Such behavior reinforced and rewarded by agonistic societies is attended by all the previously discussed physiologic mechanisms implicated in the pathogenesis of coronary atherosclerosis These include large fluctuations in blood pressure excessive catecholamine and ACTH production enhanced lipid mobilization and increased platelet aggregation

Such observations do not deny the importance of innate physiologic reactivity nor should we minimize the important influence of heredity Nevertheless if we are to talk about risk factors as phenomena which may accelerate or foster the biologic time clock of a degenerative process the psychosocial and behavioral factors discussed provide a unifying link between epidemiologic and pathophysiologic mechanisms in the study of coronary atherosclerosis We still must elucidate the intrinsic processes whereby such factors lead to the onset of clinical coronary heart disease Yet when such fundamental mechanisms are understood it should not be too difficult to understand the role of emotion and the neuroendocrine system in fostering such processes

Hypertension

Hypertension affects approximately 35 million Americans and can be traced to an identifiable cause in less than 10% of the cases Despite the widespread popular conception that an inner feeling of nervous tension is in fact hypertension we know that objective evidence for such equivalency is nonexistent However, a sizeable and diverse number of scientific observations strongly suggest that psychosocial and behavioral factors participate in the pathogenesis of hypertension The ability of adverse psychosocial situations to evoke chronic hypertension was alluded to earlier in the work of Henry While the strength of evidence in the clinical arena is less than that for objective controlled animal experiments such psychosocial factors as socioeconomic level, crime rate residential change and overcrowding have been linked with hypertension

Harburg and colleagues[1] have shown that blacks living in areas of Detroit with low ecologic stress had less hypertension than their counterparts living in high stress areas Gampel and co workers[2] have reported that there was less hypertension among rural than among urban Zulus of the latter more of those who clung to traditional cultural practices and seemed unable to successfully adapt to the demands of urban living were hypertensive In general a remarkable contrast can be found between industrialized and primitive societies that demonstrates the relative absence of hypertension in the latter Yet immigrants from primitive societies to urban communities develop hypertension with equal or greater incidence facility and severity Apropos to these observations is the comment of Ostfeld and Shekelle[3] There has been an appreciable increase in uncertainty of human relations as man has gone from the relatively primitive and more rural to the urban and industrial Contemporary man in much of the world is faced every day with people and with situations about which there is uncertainty of outcome wherein appropriate behavior is not prescribed and validated by tradition where the possiblity of bodily or psychological harm exists where running or fighting is inappropriate and where mental vigilance is called for "[3]

In reality the agonistic society of Henry and Ely s animal experiments is tantamount to the society of urbanized industrialized man However just as different genetic strains of the same species manifest different temperaments and potential for developing hypertension it is likely that similar modifiers are operative in the clinical setting Whatever provocation or stress may emanate from a social environment genetic predisposition and cognitive integration are equally important factors in the equation resulting in hypertension The mosaic theory of pathophysiol

chological components such as anxiety depression psychosocial problems and physiological variations pathophysiological aging mechanisms and genetic susceptibility are not easily assessed Clearly the most diagnostic of the available tests in the assessment of Type A behavior is the structured interview of Friedman and Rosenman None however was considered satisfactory with regard to prognostic sensitivity specificity and selectivity in predicting the advent of coronary heart disease The panel did however recommend that the structured interview be considered the most suitable as a standard at this time The Type A behavior as evaluated by the structured interview is manifested by behavioral styles of loud explosive rapid and accelerated speech with short response latency hostility and a tendency toward verbal competition

Speed impatience hostility competitive drive and a sense of an effort oriented person caught up in a joyless struggle constitute the fully developed Type A behavior pattern Glass observations that the Type A personality is vulnerable to depression are in accord with the results of a study by Thomas Ross and Duszynski of physicians with myocardial infarcts who readily became depressed even as students and likewise with the results of a study by Bruhn and colleagues [a] of the coronary prone individual as an effort oriented person whose achievements give him little satisfaction

The mechanisms through which Type A behavior operates as a risk factor and by which it facilitates the progression of coronary heart disease remain conjectural a weakness shared with all risk factors until the pathogenesis of coronary atherosclerosis is fully understood However the prevalence of certain biochemical and physiological phenomena are highly associated with fully developed Type A behavior These include elevated serum cholesterol levels elevated pre and postprandial serum triglycerides enhanced platelet aggregation faster clotting time higher excretion of norepinephrine particularly when provoked by emotional challenge a higher average serum level of corticotropin a greater insulinemic response to glucose a decreased growth hormone response to arginine and greater lability and magnitude of blood pressure response under time demand tasks [7]

It is important to make a distinction between Type A behavior and the ill defined but constantly evolving concept of coronary prone behavior Individuals manifesting Type A behavior may survive unscathed into old age attending the funerals of their younger Type B counterparts Thus the association is incomplete It is obvious that genetic perceptive and other coping factors operate to counterbalance predisposing behavioral effects in many individuals and only certain components of Type A behavior correlate with coronary heart disease Furthermore the cognitive integrative aspects of behavior and their link to pathophysiologic responses remain largely unknown

If by behavior one means the actions or reactions of man or animals under specified circumstances a recent study by Dembroski and associates illustrates the distinction between behavior in coronary patients and in non coronary control patients During a structured interview and an American history quiz they noted an increase in systolic blood pressure during the history quiz in Type B coronary patients but not in Type B controls Indeed the greatest increment of blood pressure change in either Type A or B groups was evoked in Type B myocardial infarction patients during the American history quiz Such observations suggest that we must attempt to examine and integrate the multifaceted aspects of overt psychomotor behavior with those of cognition and physiologic behavior if we are to gain further understanding of how behavioral facets translate into coronary proneness

Yet if we return to what is known and suspected concerning the pathophysiology of the other risk factors it is obvious that each represents a single manifestation of a more complex underlying process What constitutes the fundamental pathophysiology remains conjectural but it is relatively certain that the orchestration of such factors occurs in a living emotional reacting organism attempting to adapt to its environment in the interest of maintaining its own integrity A variety of psychosocial and conditioning experiments in animals point clearly to mechanisms attending the development of accelerated atherosclerosis and the neuroendocrine system is undoubtedly of pivotal importance in orchestrating the pathophysiologic mechanisms culminating in atherosclerosis

Type A behavior is recognized by its psychomotor components which in the fully developed pattern are easily recognized as signs of what

ogy proposed by Page[34] seems appropriate and useful From this vantage point the socioenvironmental association with hypertension seen in a variety of epidemiologic studies suggests that social or emotional stress may play a role in the pathogenesis of hypertension Controversies concerning the term environmental stress aside we find it more understandable and therefore more useful to view stress by its effect upon the organism in question, that effect being strain Therefore we know stress by the company it keeps namely strain It seems necessary for perceptive and cognitive processes to determine whether outside forces represent for that individual a strain inducing phenomenon There is no other apparent explanation for the old adage that beauty is in the eye of the beholder

Beyond considerations of environmental provocation psychological and behavioral aspects are also worthy of note Work by Alexander[35] suggests that the hypertensive personality may be described as an individual who frequently manifests inhibited and poorly expressed rage and anger It has been proposed that this inhibited rage or anger turned inward results in stimulation of the autonomic nervous system which causes the release of significant amounts of norepinephrine leading to acute and eventually chronic hypertension The influence of catecholamines upon renin release has already been mentioned and Esler and colleagues have reported that in psychometric testing patients with high renin hypertension exhibited suppressed hostility linked to increased sympathetic activity In these patients the hypertension was concluded to be neurogenic and possibly psychosomatic in origin Such individuals are described as withdrawn not easily communicative and tending to avoid confrontation with people even when rage is justified At times such individuals may seem obsequious in their efforts to avoid conflict in order to please those individuals with whom they are involved in interpersonal relationships

On the other hand it may be somewhat naive to postulate that personality patterns influence the autonomic nervous system and thus produce hypertension Others have suggested that this behavior may be a manifestation of an awareness by hypertensives of their hyperreactive cardiovascular system and the observed behavior represents attempts to withdraw from confrontation lest they evoke excessive and potentially harmful responses[37] • Work by some investigators suggests that hypertensive patients deny the difference between a neutral and an overtly confrontational movie drama as if in some manner they had managed to avoid perceiving what was an obvious confrontation[39]

Studies have indicated that 25% to 40% of patients with essential hypertension are characterized by higher basal circulating catecholamine levels and by higher sympathetic activity in response to postural changes[40] The identification of these patients as a separate entity is desirable since it is possible that the evolution of the hypertensive disease and response to therapy may differ in this group

Whether observations linking personality behavior and neuroendocrine mechanisms with hypertension constitute valid clues to the pathogenesis of essential hypertension or a protective response to genetic vulnerability or even a functional defect as a consequence of the disease process remains to be elucidated However a wide variety of experimental and clinical observations implicate psychosocial and behavioral factors in the phenomenon of essential hypertension The interaction between mind and environment engrafted upon a genetic substrate is a complex topic for study Yet the foregoing discussions of neuroendocrine mechanisms and consideration of the concept that essential hypertension represents specific disturbances or shifts in the bias of physiologic regulatory mechanisms is consistent with observed data in epidemiologic experimental and clinical data Since either adrenal medullary or adrenal cortical systems can lead to hypertension and are known to be activated by psychosocial stimuli with concomitant behavioral phenomena it is not too difficult to see that repeated exposure to such stimuli can lead to structural vascular thickening and mechanically increased resistance Whereas initially the imbalance is probably reversible chronically repeated and sustained arousals are likely to result in a permanent disregulatory state with fixed hypertension One cannot underestimate the importance of psychosocial and neuroendocrine elements early but it is likely that these become less significant in the later stages of hypertension

Summary

When taken together studies relating psychosocial and behavioral factors to cardiovascular disease phenomena provide justification for the conclusion that such factors are importantly

might be called competitive arousal struggle for dominance and the expected psychomotor consequences of the fight or flight mechanism With regard to the previously mentioned animal studies concerning alterations in the environment it seems reasonable to suspect that environmental stress and sociocultural factors importantly influence the type of behavior observed Industrialized western societies have in common a depersonalized complexity and reward system for the effective competitor In general these societies tend to reward those who are time urgent and aggressive Thus in some ways there is a curious resemblance between Henry and Ely s studies [9] of an agonistic society in mice and contemporary industrialized societies

Over the last 30 years an increasing proportion of hypertensive subjects have come to be treated with antihypertensive drugs The first drugs used though life saving in their day were too toxic and were replaced by others which produced fewer side effects Knowledge of the sites and mechanisms of action of antihypertensive agents has greatly increased Newer agents have been developed for greater selectivity However there has not been a corresponding growth in the understanding of the pathogenesis of hypertension nor is it yet feasible in the clinic to analyze the mechanisms giving rise to hypertension in individual patients Indeed it has been claimed that the concept of prospectively individualizing antihypertensive therapy remains largely hypothetical These considerations may help to explain why despite a steady flow of interesting new antihypertensive substances from the pharmaceutical industry clinical trials have often failed to confirm that greater specificity in drug action achieves a better therapeutic result We appear to have reached a plateau in therapeutic efficacy It may then be asked does a precise knowledge of the specific sites and mechanisms of drug action really help in choosing treatment for the individual patient with high blood pressure? Further what justification exists for prescribing the more selective drugs?

We propose that understanding the action of an antihypertensive agent helps to predict and recognize its side effects to avoid adverse interactions with other drugs and to obtain additive hypotensive effects by combining it with drugs acting elsewhere Such information is integral to the design of systems of stepped care therapy through which individualization of treatment though empirical can proceed along rational lines In this review we will outline what is known about the modes of action the side effects and the applications of currently available antihypertensive drugs and will analyze their contributions to a system of stepped care therapy

I Mechanisms of action and interaction of antihypertensive drugs

Antihypertensive drugs fall into four main groups diuretics angiotensin inhibitors vascular smooth muscle relaxants and sympatholytic drugs The clinical relevance of the angiotensin inhibitors is yet to be clearly defined and they are restricted to investigational use at present

1 Diuretics These act principally by causing renal loss of sodium and water with reduction in intravascular volume and cardiac output In the early stage of diuretic therapy the hypotensive effect reflects mainly a fall in cardiac output[3] In the later stage secondary adjustments restore cardiac output but blood pressure control is maintained through peripheral vasodilatation Discussion of the differences between the diuretics in their renal tubular actions is beyond the scope of this paper but may be found in the review by Seely and Dirks[5]

2 Angiotensin inhibitors act by preventing the effects of the renin angiotensin system upon vascular smooth muscle and possibly upon the adrenal cortex kidney and brainstem Angioten

might be called competitive arousal struggle for dominance and the expected psychomotor consequences of the fight or flight mechanism With regard to the previously mentioned animal studies concerning alterations in the environment it seems reasonable to suspect that environmental stress and sociocultural factors importantly influence the type of behavior observed Industrialized western societies have in common a depersonalized complexity and reward system for the effective competitor In general these societies tend to reward those who are time urgent and aggressive Thus in some ways there is a curious resemblance between Henry and Ely s studies[9] of an agonistic society in mice and contemporary industrialized societies

Hypertension

Hypertension affects approximately 35 million Americans and can be traced to an identifiable cause in less than 10 % of the cases Despite the widespread popular conception that an inner feeling of nervous tension is in fact hypertension we know that objective evidence for such equivalency is nonexistent However, a sizeable and diverse number of scientific observations strongly suggest that psychosocial and behavioral factors participate in the pathogenesis of hypertension. The ability of adverse psychosocial situations to evoke chronic hypertension was alluded to earlier in the work of Henry While the strength of evidence in the clinical arena is less than that for objective controlled animal experiments, such psychosocial factors as socioeconomic level, crime rate residential change, and overcrowding have been linked with hypertension

Harburg and colleagues[11] have shown that blacks living in areas of Detroit with low ecologic stress had less hypertension than their counterparts living in high stress areas. Gampel and co workers[12] have reported that there was less hypertension among rural than among urban Zulus, of the latter more of those who clung to traditional cultural practices and seemed unable to successfully adapt to the demands of urban living were hypertensive In general a remarkable contrast can be found between industrialized and primitive societies that demonstrates the relative absence of hypertension in the latter Yet immigrants from primitive societies to urban communities develop hypertension with equal or greater incidence facility and severity Apropos to these observations is the comment of Ostfeld and Shekelle[53] There has been an appreciable increase in uncertainty of human relations as man has gone from the relatively primitive and more rural to the urban and industrial. Contemporary man in much of the world is faced every day with people and with situations about which there is uncertainty of outcome wherein appropriate behavior is not prescribed and validated by tradition where the possibility of bodily or psychological harm exists where running or fighting is inappropriate and where mental vigilance is called for [53]

In reality the agonistic society of Henry and Ely s animal experiments[20] is tantamount to the society of urbanized industrialized man. However just as different genetic strains of the same species manifest different temperaments and potential for developing hypertension it is likely that similar modifiers are operative in the clinical setting Whatever provocation or stress may emanate from a social environment genetic predisposition and cognitive integration are equally important factors in the equation resulting in hypertension The mosaic theory of pathophysiol

ogy proposed by Page[84] seems appropriate and useful From this vantage point the socioenvironmental association with hypertension seen in a variety of epidemiologic studies suggests that social or emotional stress may play a role in the pathogenesis of hypertension Controversies concerning the term environmental stress aside we find it more understandable and therefore more useful to view stress by its effect upon the organ in question that effect being strain Therefore we know stress by the company it keeps namely strain It seems necessary for perceptive and cognitive processes to determine whether outside forces represent for that individual a strain inducing phenomenon There is no other apparent explanation for the old adage that beauty is in the eye of the beholder

Beyond considerations of environmental provocation psychological and behavioral aspects are also worthy of note Work by Alexander[85] suggests that the hypertensive personality may be described as an individual who frequently manifests inhibited and poorly expressed rage and anger It has been proposed that this inhibited rage or anger turned inward results in stimulation of the autonomic nervous system which causes the release of significant amounts of norepinephrine leading to acute and eventually chronic hypertension The influence of catecholamines upon renin release has already been mentioned and Esler and colleagues[8] have reported that in psychometric testing patients with high renin hypertension exhibited suppressed hostility linked to increased sympathetic activity In these patients the hypertension was concluded to be neurogenic and possibly psychosomatic in origin Such individuals are described as withdrawn not easily communicative and tending to avoid confrontation with people even when rage is justified At times such individuals may seem obsequious in their efforts to avoid conflict in order to please those individuals with whom they are involved in interpersonal relationships

On the other hand, it may be somewhat naive to postulate that personality patterns influence the autonomic nervous system and thus produce hypertension Others have suggested that this behavior may be a manifestation of an awareness by hypertensives of their hyperreactive cardiovascular system and the observed behavior represents attempts to withdraw from confrontation lest they evoke excessive and potentially harmful responses[8, 9] Work by some investigators suggests that hypertensive patients deny the difference between a neutral and an overtly confrontational movie drama as if in some manner they had managed to avoid perceiving what was an obvious confrontation[89]

Studies have indicated that 25% to 40% of patients with essential hypertension are characterized by higher basal circulating catecholamine levels and by higher sympathetic activity in response to postural changes[90] The identification of these patients as a separate entity is desirable since it is possible that the evolution of the hypertensive disease and response to therapy may differ in this group

Whether observations linking personality behavior and neuroendocrine mechanisms with hypertension constitute valid clues to the pathogenesis of essential hypertension or a protective response to genetic vulnerability or even a functional defect as a consequence of the disease process remains to be elucidated However a wide variety of experimental and clinical observations implicate psychosocial and behavioral factors in the phenomenon of essential hypertension The interaction between mind and environment engrafted upon a genetic substrate is a complex topic for study Yet the foregoing discussions of neuroendocrine mechanisms and consideration of the concept that essential hypertension represents specific disturbances or shifts in the bias of physiologic regulatory mechanisms is consistent with observed data in epidemiologic experimental and clinical data Since either adrenal medullary or adrenal cortical systems can lead to hypertension and are known to be activated by psychosocial stimuli with concomitant behavioral phenomena it is not too difficult to see that repeated exposure to such stimuli can lead to structural vascular thickening and mechanically increased resistance Whereas initially the imbalance is probably reversible chronically repeated and sustained arousals are likely to result in a permanent disregulatory state with fixed hypertension One cannot underestimate the importance of psychosocial and neuroendocrine elements early but it is likely that these become less significant in the later stages of hypertension

		Atenolol	

Gangl on blocking drug exclud d
†Neuron blocking drugs
‡Alpha adrenergic c ptor bl cki g drugs
§Combined alpha nd beta adrenergi recepto blocking drug

sin antagonists competitively block the action of angiotensin II on its receptors whereas converting enzyme inhibitors interfere with the conversion of angiotensin I to angiotensin II Unfortunately controversy surrounds the mode of action of the potentially most useful member of this group the converting enzyme inhibitor captopril This drug the only angiotensin inhibitor yet developed which is effective by the oral route, also potentiates the kinin system and possibly produces its hypotensive action in part through this or other still undefined pharmacologic mechanisms Nevertheless a recent review of 19 hypertensive patients treated for periods of up to 6 months has shown that the blood pressure reduction produced by captopril was correlated both with the pretreatment plasma renin activity and with the suppression of urinary aldosterone excretion

3 Vascular smooth muscle relaxant drugs alter cellular calcium flux and cause direct vasodilatation[8] Their actions are independent of alpha and beta adrenoreceptors

4 Sympatholytic drugs interfere with neurohumoral transmission at various points in the sympathetic nervous system This the large group can be divided on a pharmacological b into many classes However from a therapeu viewpoint the simple classification shown in Table I will suffice

The ways in which the centrally acting cla lower blood pressure are still unclear but they have in common the ability to reduce central sympathetic outflow This may be demonstrated most graphically by showing the decreased rate of spontaneous firing of pre ganglionic sympathetic neurons after administration of the drug into the cerebral ventricular system[9] In the case of methyldopa clonidine and clonidine like drugs (guanabenz tiamenidine and guanfacine) the reduction of sympathetic traffic appears to result from an alpha adrenergic agonist effect operating on the central inhibitory pathways leading to the vasomotor center, although other central mecha nisms of action have been proposed for clo dine[10] Reserpine causes depletion of catechol amines from both central and sympathetic neu rons[1] The action of methyldopa is thought

Appraisal and reappraisal of cardiac therapy

Over the last 30 years an increasing proportion of hypertensive subjects have come to be treated with antihypertensive drugs The first drugs used though life-saving in their day were too toxic and were replaced by others which produced fewer side effects Knowledge of the sites and mechanisms of action of antihypertensive agents has greatly increased Newer agents have been developed for greater selectivity However there has not been a corresponding growth in the understanding of the pathogenesis of hypertension nor is it yet feasible in the clinic to analyze the mechanisms giving rise to hypertension in individual patients Indeed it has been claimed that the concept of prospectively individualizing antihypertensive therapy remains largely hypothetical These considerations may help to explain why despite a steady flow of interesting new antihypertensive substances from the pharmaceutical industry clinical trials have often failed to confirm that greater specificity in drug action achieves a better therapeutic result We appear to have reached a plateau in therapeutic efficacy It may then be asked does a precise knowledge of the specific sites and mechanisms of drug action really help in choosing treatment for the individual patient with high blood pressure? Further what justification exists for prescribing the more selective drugs?

We propose that understanding the action of an antihypertensive agent helps to predict and recognize its side effects to avoid adverse interactions with other drugs and to obtain additive hypotensive effects by combining it with drugs acting elsewhere Such information is integral to the design of systems of stepped care therapy through which individualization of treatment though empirical can proceed along rational lines In this review we will outline what is known about the modes of action the side effects and the applications of currently available antihypertensive drugs and will analyze their contributions to a system of stepped care therapy

I Mechanisms of action and interaction of antihypertensive drugs

Antihypertensive drugs fall into four main groups diuretics angiotensin inhibitors vascular smooth muscle relaxants and sympatholytic drugs The clinical relevance of the angiotensin inhibitors is yet to be clearly defined and they are restricted to investigational use at present

1 Diuretics These act principally by causing renal loss of sodium and water with reduction in intravascular volume and cardiac output In the early stage of diuretic therapy the hypotensive effect reflects mainly a fall in cardiac output [3] In the later stage secondary adjustments restore cardiac output but blood pressure control is maintained through peripheral vasodilatation Discussion of the differences between the diuretics in their renal tubular actions is beyond the scope of this paper but may be found in the review by Seely and Dirks [5]

2 Angiotensin inhibitors act by preventing the effects of the renin angiotensin system upon vascular smooth muscle and possibly upon the adrenal cortex kidney and brainstem Angioten

Table II *Homeostatic reflexes opposing blood pressure control*

1	Baroreceptor reflexes
	(a) Alpha adrenoceptor mediated vasoconstriction
	(b) Beta adrenoceptor mediated cardiac stimulation
2	Renal retention of salt and water
3	Renin angiotensin system

been proposed [18] However agents recently developed for beta 1 receptor blocking selectivity (metoprolol, atenolol) have proved to be at least as effective in reducing blood pressure as the non selective beta 1 and beta 2 receptor antagonists Thus it has been possible to decrease some of the undesired effects of beta 2 receptor blockade without loss of antihypertensive efficacy

Proper application of drugs of the sympatholytic group may be of critical importance in the treatment of severe hypertension because they counteract the baroreceptor mediated homeostatic reflexes which combat the antihypertensive effect of the other groups of drugs (see Table II) While there are several types of drugs acting at different sites which can interrupt sympathetic neural traffic to the vascular alpha adrenoreceptors the only antihypertensive agents which block the cardiac limb of the baroreceptor reflex are the beta adrenergic blockers It should be noted that they serve this important function in addition to exerting a hypotensive effect of their own Agents which diminish reflex cardioacceleration in less specific ways include clonidine (by central vagotonic and peripheral pre synaptic alpha receptor agonist interactions) and indoramin (by direct negative chronotropic effect)

A second homeostatic function that may interfere with blood pressure control is the renal retention of salt and water which occurs whenever kidney perfusion pressure drops This mechanism operates tending to restore the blood pressure to a high level when potent smooth muscle relaxant or sympatholytic drugs are used without adequate diuretic therapy The term false tolerance has been coined to emphasize the subtle nature of this problem which can exist in the absence of demonstrable edema To overcome such tolerance it may be necessary to use large doses of loop diuretics especially in patients with renal impairment

Another renal mechanism which can override the effects of antihypertensive agents is activation of the renin angiotensin system Increased circulating levels of renin and angiotensin together with an increased hypotensive response to angiotensin inhibitors are found during treatment with diuretics or smooth muscle relaxant drugs Conversely maintenance therapy with beta blockers reduces plasma renin activity to an extent determined mainly by the intrinsic sympathomimetic activity of the particular beta blocker used [1] and the influence of concomitant therapy In general the centrally acting sympatholytic drugs also decrease renin release where the peripherally acting class have a variable effect

To summarize the primary action of hypotensive drugs can be opposed by homeostatic reflexes listed in Table II Failure to respond to therapy may reflect the influence of one or more of these It is often possible to recognize the particular mechanism operative in an individual patient For example during treatment with a potent vasodilator agent the occurrence of edema weight gain or an increase in measured blood volume would point to the need for additional diuretic therapy whereas the presence of tachycardia and a high cardiac output state might call for the addition of a beta blocker to the therapeutic regimen

II Side effects Relevance to the application of particular drugs

A thorough knowledge of the side effects encountered with various antihypertensive drugs is essential for choosing the most suitable agent for each individual patient Side effects which can be anticipated and which may influence such choice are discussed below

A Diuretics

1 *Hypovolemia* A fall in blood volume may occur immediately after the introduction of diuretic therapy or with the intermittent use of a diuretic Because of the associated hazard of hypotension and blood hyperviscosity, a risk of precipitating cerebral ischemia exists in patients with cerebrovascular disease Thus the potent diuretics such as furosemide should rarely be used in elderly subjects and diuretic therapy avoided altogether in patients with transient ischemic attacks

2 *Hyperuricemia* Most diuretics tend to raise serum uric acid concentration probably of an increased passive reabsorption of urate

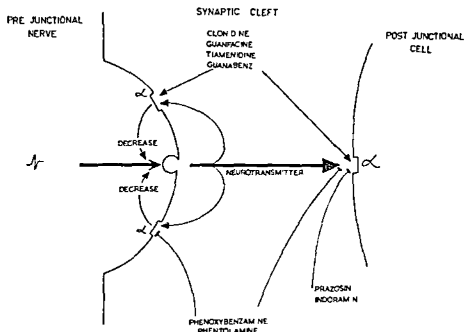

Fig 1 Actions of some antihypertensive agents on the alpha adrenergic receptors of the peripheral neuro-effector junction. → agonist effect ⊣ receptor blockade

depend on its active metabolites including alpha methylnorepinephrine which has a potent alpha agonist effect centrally but little peripheral effect Clonidine and its congeners have been shown to exert a potent agonist effect at the pre-synaptic alpha receptors of the sympathetic neuroeffector junction (see Fig 1) This property which causes a diminished release of neurotransmitter may contribute to the decrease in circulating catecholamines observed in patients treated with clonidine[13] or guanfacine[1] These agents also have a relatively weak peripheral post junctional alpha agonist effect which may result in an initial pressor response following their intravenous administration[1]

Those antihypertensive drugs which are known to have a predominantly peripheral site of action include the adrenergic neuron blocking agents and the alpha adrenergic receptor blockers (Table I) The ganglion blockers which interfere with parasympathetic as well as sympathetic pathways are now of historical interest only and have no part in the present-day treatment of hypertensive cardiovascular disease (although they still have a limited role in blood pressure control during anesthesia and in the treatment of aortic dissection e g trimethaphan) The adrenergic neuron blockers are taken up into the nerve ending by uptake the mechanism responsible for re uptake of neurotransmitter norepinephrine They displace the neurotransmitter in storage granules and also interfere directly with the coupling of nerve impulses to exocytotic release Alpha adrenergic receptor blockers lower blood pressure by preventing the agonist effect of neurotransmitter upon the post junctional alpha receptors at the sympathetic myoneural junctions of vascular smooth muscle (Fig 1) They may be classed as relatively selective (e g prazosin) or non selective (e g phenoxybenzamine) depending upon the degree to which the pre junctional alpha receptors are also blocked It has been suggested that pre junctional alpha adrenergic blockade which interferes with the negative feedback control of neurotransmitter release is disadvantageous and may account for the greater problems encountered with phenoxybenzamine in clinical practice than with prazosin[6] Labetalol a new antihypertensive agent with both alpha and beta adrenergic receptor blocking actions is more potent at beta receptors than at alpha receptors in man but it is not known which of these effects is of the greater importance in reducing blood pressure during chronic oral administration[1]

It has not been established how beta adrenoceptor blocking drugs lower blood pressure Various central and peripheral sites of action have

severe fluid retention[41,43] Pericardial effusion may occur without generalized edema[44] Hypertrichosis occurs in both sexes and the growth of facial hair commonly causes distress in women However calcium thioglycolate depilatory cream is effective in removing unwanted facial hair and causes little or no skin irritation thus allowing continuation of minoxidil therapy in women with hypertension resistant to other agents[45]

DIAZOXIDE Diazoxide has had its widest use in hypertension as an injectable solution given intravenously in a dose of 150 to 300 mg for the control of hypertensive crises A rapid fall in blood pressure tachycardia transient hyperglycemia and stimulation of renin release occur after injection[46] The latter effect has proved useful in diagnosing renovascular hypertension[4] Because it causes reflex tachycardia and increases cardiac output diazoxide should not be used to treat the severe hypertension associated with aortic dissection[48] The chronic administration of diazoxide by mouth although effective in controlling severe hypertension associated with renal failure is diabetogenic in about two thirds of subjects and may induce extrapyramidal symptoms[50]

VERAPAMIL Verapamil has received much more attention as an antianginal and antiarrhythmic compound than as an antihypertensive agent However its potent smooth muscle relaxant effect produces a fall in blood pressure[51] when the drug is administered orally or intravenously Constipation due to the relaxation of visceral smooth muscle is common[51] Since verapamil impairs atrioventricular conduction and myocardial contractility it should not be given to patients with heart block or cardiac failure nor should it be used in combination with beta adrenergic blocking drugs[52]

NIFEDIPINE This new vasodilator which was originally proposed for use in coronary vascular disease has a potent hypotensive action which lasts for 6 to 8 hours after oral or sublingual administration of a 20 mg dose[53] Side effects reported with its use include sensations of heat in the face and limbs and ankle edema Compared to verapamil nifedipine has a much less pronounced effect on the heart and may be used in combination with a beta blocking agent

SODIUM NITROPRUSSIDE Infusion of nitroprusside is an alternative to the use of diazoxide infusion in hypertensive crises Constant monitoring of blood pressure and plasma thiocyanate concentration is required to maintain blood pressure control and to prevent toxic encephalopathy[55] These objectives can be facilitated by the use of a microprocessor to control the rate of infusion[6]

D Sympatholytic drugs

a Centrally acting sympatholytic agents

1 SIDE EFFECTS RELATED TO CENTRAL DEPRESSANT ACTIVITY AND INTERACTIONS WITH PSYCHOTROPIC THERAPY All centrally acting antihypertensive drugs may cause significant daytime sedation which often improves spontaneously as therapy continues Those in widespread clinical use (reserpine methyldopa and clonidine) have each been associated with an appreciable incidence of severe depression Tricyclic antidepressant drugs may interfere with the antihypertensive actions of clonidine[5,58] or methyldopa[?] probably due to interactions at the central alpha adrenoreceptors in the brainstem. Unfavorable interactions may also occur between monoamine oxidase inhibitors and methyldopa. In view of the problems which can arise during the management of depressive patients receiving centrally acting antihypertensive agents they should not be prescribed for patients with a previous history of endogenous depression except in the exigency of known resistance to peripherally acting antihypertensive agents

2 WITHDRAWAL REACTIONS In patients treated with clonidine for severe hypertension abrupt withdrawal of this agent can provoke a syndrome characterized by acute hypertension tachycardia and other features of sympathetic discharge[59,6] Similar reactions have been noted after acute withdrawal of methyldopa guanabenz[64] and guanfacine[6] Considerable disagreement exists however concerning the incidence magnitude and clinical importance of true overshoot hypertension during withdrawal reactions There have been numerous case reports of severe and occasionally disastrous hypertensive crises after stopping clonidine and three groups have reported features of sympathetic overactivity with or without overshoot hypertension even after controlled withdrawal of the drug[60-62] Conversely others have found no evidence of sympathetic overactivity after withdrawal of the drug apart from raised urinary norepinephrine excretion[66] All these studies have been criticized on various grounds including lack of pretreatment blood pressure data and insufficiently close monitoring during the withdrawal phase The obvi...

the kidney accompanying compensatory shifts of proximal tubular fluid. In the case of ticrynafen this tendency is countered by specific inhibition of the re absorption of both filtered and secreted urate.[3] Clinical gout is precipitated in only a small proportion of patients who develop hyperuricemia as a result of treatment with a diuretic. In such individuals or in those who present with a history of gout of hyperuricemia a number of therapeutic strategies are available: a. Avoid the use of diuretics completely. b. Use ticrynafen. c. Use a diuretic plus probenecid (which inhibits renal tubular reabsorption of urate). d. Use a diuretic plus allopurinol, which inhibits the production of uric acid. If there is evidence of increased uric acid turnover, options (a) and (d) are preferable to (b) and (c), both of which promote uricosuria and can cause crystalluria.

3. *Changes in serum potassium levels.* All diuretics except those of the potassium conserving class (Table I) increase distal tubular potassium secretion and can lead to an appreciable fall in serum potassium concentration. This may have serious consequences in patients receiving digitalis or in those with primary aldosteronism, liver disease or pre existing potassium depletion. However diuretic induced hypokalemia rarely produces problems in patients with uncomplicated hypertension. Potassium conserving diuretics tend to produce hyperkalemia when given to patients with diabetes mellitus[28] or impaired renal function. Means of potassium supplementation and their relative efficacy and safety have been reviewed recently.[29]

4. *Carbohydrate intolerance.* Thiazide diuretics may cause a rise in blood sugar in diabetic patients[3] and may occasionally induce hyperglycemia and glycosuria in previously normal people.[3] Carbohydrate intolerance has also been reported with the use of loop diuretics.[3] The mechanism is not wholly understood[31] but there is evidence for both impaired pancreatic insulin release and defective glucose utilization by peripheral tissues. Thus a relative contraindication to diuretic therapy exists in patients with diabetes mellitus or known carbohydrate intolerance. This however should not countermand the use of diuretics in such subjects when their hypertension is resistant to other therapy or is complicated by fluid retention.

5. *Hypercalcemia.* Chronic administration of thiazide and related diuretics reduces calcium excretion by a mechanism analogous to that which pertains to urate.[3] A rise in serum calcium may result. This is usually minor but could be deleterious in patients with pre existing hypercalcemia due to metabolic disorders such as hyperparathyroidism.

B. Angiotensin inhibitors. Administration of the oral converting enzyme inhibitor captopril has induced febrile reactions,[7] rashes,[7] loss of taste sensation,[3] and reversible renal failure.[36] Intravenous administration of the angiotensin analog saralasin acetate has been associated with pheochromocytoma crisis occurring during the infusion and rebound hypertension with encephalopathy occurring one to three hours after stopping the infusion.[3] In general angiotensin inhibitors may produce severe depressor responses in conditions of strong angiotensin II dependency such as extreme sodium depletion, renovascular hypertension and intercurrent therapy with diuretic or vasodilator drugs.[39]

C. Vascular smooth muscle relaxants

1. *Side effects common to all smooth muscle relaxant drugs.* The symptoms of a hyperkinetic circulatory state (flushing, headache, and pounding in the ears or chest) may be observed with any drug which produces vasodilatation by a direct action on arteriolar smooth muscle. Tachycardia and fluid retention resulting from unopposed homeostatic adjustments (already outlined) are also common to all drugs of this group. All these symptoms may be countered by the adjunctive use of sympatholytic or diuretic agents, this being essential with the more potent drugs of the group such as minoxidil.

2. *Side effects peculiar to particular smooth muscle relaxant drugs.*

HYDRALAZINE. The most important side effect of hydralazine is the development of a syndrome resembling systemic lupus erythematosus. The drug is best avoided in patients with a family history of lupus and dosage should be restricted to a ceiling of 200 mg per day in known slow acetylators or in subjects with renal impairment. Other side effects specific to hydralazine have been reviewed by Alarcon Segovia and associates.

MINOXIDIL. This drug, the most potent of the orally active peripheral vasodilators, is potentially life saving for refractory hypertension coupled with progressive renal impairment but may cause

Table III Some contraindications to the use of certain drugs in hypertension

Condition	Drugs contraindicated
Gout Hyperuricemia Hypokalemia	Thiazide diuretics Loop diuretics
Hypercalcemia	Thiazide diuretics
Depression	Reserpine methyldopa Clonidine
Poor drug compliance	Clonidine
Transient ischemic attacks Old age	Potent diuretics Adrenergic neuron blockers Alpha adrenergic blockers
Treatment with tricyclic substances	Adrenergic neuron blockers Clonidine methyldopa
Angina pectoris Tachycardia	Smooth muscle relaxants Alpha adrenergic blockers
Cardiac failure Bradyarrhythmia A V block	Beta adrenergic blockers Verapamil
Asthma Insomnia	Beta adrenergic blockers
Raynaud s syndrome Calf Claudication	Non selective beta blockers

Except in the presence of beta adrenergic blockade

lower in incidence with beta 1 selective blockers than with those of indiscriminate beta 1 and beta 2 affinity However increased selectivity has resulted in limited gains because receptor selectivity is relative and not absolute and also because most organs appear to have populations of both beta 1 and beta 2 receptors despite a dominance of one type or the other Presumably the cardioselective drugs should have less tendency to produce bronchospasm or exacerbate symptoms of peripheral vascular disease However severe asthmatic reactions and Raynaud s phenomenon have been reported with the use of these selective agents All beta blockers should be avoided in asthmatic patients or in subjects who give a history of persistent wheeze during respiratory infections and similarly in patients with peripheral gangrene or other evidence of severe vasospasm Beta blockers are not contraindicated in hypertensive diabetic subjects except perhaps those whose control is brittle or those prone to frequent hypoglycemic reactions Beta 1 selective blockers are preferable for use in diabetic patients[80] The question of whether beta 1 selectivity improves diastolic blood pressure control

Table IV Some indications for the use of [illegible] drugs in hypertension

Condition	Drugs ind[illegible]
Cardiac failure Edema	Diuretics (any)
Hyperuricemia	Ticrynafen
Hypokalemia	K -conserving diuretics
Migraine	Clonidine Beta-adrenergic blockers
Angina Palpitations Ectopic beats Arrhythmias (not all)	Beta adrenergic blockers Verapamil
Recent myocardial infarction	Beta adrenergic blockers
Essential tremor	Propranolol
Severe cardiac failure	Prazosin Hydralazine Sodium nitroprusside Nifedipine

during stress is unresolved Although exog[illegible] epinephrine produces less rise in diastolic pres[illegible] during beta 1 blockade than during non select[illegible] beta blockade this phenomenon does not nece[illegible] sarily hold for situations of endogenous catech[illegible] amine release from the adrenal medulla or [illegible] pathetic nerve terminals[a]

III A system of stepped-care therapy

The questions to be considered in selecting [illegible] treatment for a given patient with hyperten[illegible] are

1 What characteristics of the patient cons[illegible] tute indications or contraindications for the us[illegible] of particular drugs?

2 Having decided which drugs suit the patie[illegible] what options exist for their use in appropria[illegible] combinations if combined therapy proves nece[illegible] sary to control the hypertension?

The first of these decisions involves pati[illegible] drug matching while the second involves th[illegible] matching of drug to drug in combinations wh[illegible] achieve additive hypotensive effects but mi[illegible] mize side effects Contraindications to spec[illegible] drugs and classes of drugs have been discussed and some of the more important examples [illegible] listed in Table III Certain indications for partic[illegible] ular drugs are given in Table IV

These considerations form a background [illegible]

difficulties in carrying out and interpreting appropriate experiments in hypertensive patients has pointed to the need for controlled studies in normotensive subjects and in experimental animals We have demonstrated significant overshoots in blood pressure and heart rate 16 to 24 hours after even single doses of clonidine or guanfacine in normotensive rats [7, 68] Another group has confirmed these findings although they failed to demonstrate overshoot in hypertensive rats [9]

It is the authors opinion that the hazards of clonidine withdrawal are real enough to warrant *avoiding this drug in patients who have a history* of poor compliance with drug therapy If chronic oral medication with clonidine is interrupted by acute gastrointestinal disorders or the need for general anesthesia therapy may be continued by the intramuscular route [7]

3 OTHER RELEVANT SIDE EFFECTS OF CENTRALLY ACTING ANTIHYPERTENSIVE AGENTS Drugs in this class may occasionally cause sexual dysfunction in males and so threaten compliance Since bowel disturbances may result from treatment with methyldopa or clonidine, it is preferable to avoid using these agents in patients with enterocolitis Reserpine especially when given in large doses may aggravate peptic ulcer disease Postural hypotension occurs infrequently with both methyldopa and clonidine but is more prominent with guanabenz which has a subsidiary peripheral adrenergic neuron blocking effect [7]

b *Peripherally acting sympatholytic agents*

1 SIDE EFFECTS OF NEURON BLOCKING DRUGS The side effects of this class which is long established in clinical therapy are well known and will not be detailed here The most important are postural hypotension diarrhea and interruption of the ejaculation reflex The antihypertensive action of neuron blockers is severely impaired by tricyclic antidepressant therapy [72] probably through competition for the neuronal uptake process

2 SIDE EFFECTS OF ALPHA ADRENERGIC RECEPTOR BLOCKING DRUGS Postural hypotension has been the most frequent and troublesome side effect with alpha adrenoceptor antagonists Hence it is inadvisable to use these drugs in the elderly or in subjects with known cerebrovascular or coronary insufficiency Particularly severe reactions have been reported after the initial dose of prazosin *or as a response to dosage increments* of this agent This first dose phenomenon is aggravated by prior sodium depletion[7] or by the presence of renal failure [4] It has been attributed to selective blockade of visceral sympathetic activity [73] but usually subsides despite continued therapy The problem is minimized by starting with a small dose in the evening [16] However postural hypotension and tachycardia persist during chronic therapy in a small proportion of patients and may necessitate withdrawal of the drug [1] Postural hypotension necessitated withdrawal of labetalol in three of 16 patients in one series treated with this combined alpha and *beta receptor blocking drug and has been a* prominent side effect in other recent trials with labetalol Failure of ejaculation occurs occasionally with labetalol but has not been definitely associated with prazosin or indoramin The use of indoramin even in low doses as part of a multiple drug regimen is limited by its central depressant action The other members of this class of drugs uncommonly cause central side effects and their acceptance by patients has been generally good except in the case of phenoxybenzamine [8]

3 SIDE EFFECTS OF BETA ADRENERGIC RECEPTOR BLOCKING DRUGS We will not attempt to give a comprehensive description of the side effects of this class which have been well reviewed elsewhere However certain guidelines may be helpful in selecting therapy

(i) The side effects of beta blockers can be readily predicted for the most part on the basis of their interference with beta receptor mediated sympathetic transmission to the heart bronchi and peripheral blood vessels The central nervous and metabolic effects of these drugs are less well understood

(ii) Since these agents interrupt sympathetic drive to the heart they should not be used in patients with heart failure bradyarrhythmias or atrioventricular conduction block

(iii) All drugs of this class reduce maximal exercise performance and tend to induce mild lassitude These effects are a consequence mainly of cardiac beta adrenergic blockade although peripheral vasoconstriction mediated by beta 2 receptor antagonism and central nervous depression may be contributory Beta blockers may prove unacceptable to patients who engage in competitive sports

(iv) Most other side effects including bronchospasm peripheral vasospasm and potentiation of *hypoglycemia in diabetic subjects* appear to

zine Thus if the addition of relatively small doses of either prazosin or hydralazine fails to achieve blood pressure control it may be necessary to increase the dose of methyldopa debrisoquine or clonidine above the levels indicated at Step 2

A further alternative at Step 3 is to substitute labetalol a combined alpha and beta adrenergic blocking drug for the beta blocker previously administered

Step 4 This step should be required only in the most resistant cases of severe chronic hypertension associated with evidence of progressive retinal renal or cardiac damage Two new elements are added (1) minoxidil a potent but potentially toxic smooth muscle relaxant drug the use of which is restricted by governmental regulation in most countries (as is that of oral diazoxide which is more toxic and probably not as frequently effective) (2) a dose finding escalation of diuretic therapy with furosemide bumetanide or ethacrynic acid The initial dose of minoxidil should be 2.5 mg twice a day increasing by increments of 2 5 mg twice a day to a maximum of 40 mg /day Beta blocker therapy is a prerequisite in order to counteract reflex tachycardia Doses of loop diuretic well beyond the conventional may be required to overcome the tendency to salt and water retention associated with hypertensive nephrosclerosis and minoxidil therapy, in the case of furosemide up to 500 mg twice a day may be required

Conclusions

The deployment of the newer more selective drugs for the treatment of hypertension can be analyzed from several points of view Ideally these drugs should be applied specifically in each case to correct the perturbation inducing hypertension Because the pathogenesis of most forms of hypertension is not clearly understood such a mechanistic approach is rarely possible at present However understanding the mode of action and the side effects of an antihypertensive drug does allow to a limited extent appropriate matching between drug and patient Even more importantly it allows the drug to be fitted into a system of stepped care therapy in which antihypertensive agents are combined for synergistic effects These effects depend upon the correction by one drug of the homeostatic reflexes activated by another and allow the toxicity produced by single agents in high dosage to be avoided

guide the choice of options from the following stepped-care system which is summarized in Table V.

Steps 1 and 2 A thiazide diuretic remains the best choice for treating most mild cases of hypertension and as the initial component of stepped care therapy. More potent diuretics may be required for patients with hypertension and renal impairment or congestive heart failure. Until the role of ticrynafen in treating hyperuricemic hypertensive subjects has been established it is probably wisest to withhold diuretic treatment in patients with gout or hyperuricemia and to rely on the use of Step 2 agents.

The reasons for selecting a beta blocker above the alternatives given in Step 2 are twofold. First the incorporation of agents at Steps 3 and 4 is facilitated by prior beta blockade. Second the symptoms encountered with beta blocker therapy are usually mild and show little relationship to dose within the conventional therapeutic range (e.g., for propranolol 20 to 480 mg/day). Thus once therapy with a small dose is shown to be well tolerated dosage may be escalated with little fear of provoking new side effects. In mild to moderate hypertension adequate blood pressure control may be obtained by giving medication once per day. In severe cases it should be given twice per day except in the case of atenolol which has a longer duration of action.[3] Until more toxicological data have accumulated to show that beta 1 blockers are as safe as the established agents of the non selective type they should not necessarily be regarded as having superseded the latter. However as already outlined they are preferred in hypertensive subjects with diabetes or peripheral vasospasm. The conventional dose range for metoprolol is from 50 to 400 mg/day and for atenolol it is from 50 to 200 mg/day. Since the dose-response curve for atenolol flattens above 200 mg/day doses higher than this are not recommended.[3]

In patients with heart failure asthma or other contraindications to beta blockers there is a wide choice of alternatives including the three shown in Table V. We do not recommend using any of these agents in maximal dosages as it is usually better to go to Step 3 instead adding an additional agent. Thus the dosage ceiling recommended for methyldopa at Step 2 is about 1 gram/day for appreciable central depressant symptoms are commonly encountered with higher doses. The

Table V A stepped-care system of antihypertensive drug treatment

Step 1.	Diuretic		
Step 2	Diuretic + β blocker		
	Or Methyldopa	}	Low Dose
	Or Debrisoquine	}	Low Dose
	Or Clonidine	}	Low Dose
Step 3	Diuretic + β blocker + prazosin		
	Or other Or Hydralazine		
Step 4.	Loop diuretic + β blocker + minoxidil		

ceiling suggested at Step 2 for clonidine is 0.45 mg/day and for debrisoquine it is 20 mg/day. In mild to moderate hypertension only prazosin (up to 6 mg/day) or hydralazine (up to 100 mg/day) are also suitable alternatives to beta blockade.

Step 3 The prior introduction of a diuretic and a beta blocker allows the commencement of a peripheral vasodilator at Steps 3 and 4 without the development of cardiac stimulation or refractoriness due to secondary fluid retention or hyperreninemia. The synergistic actions of propranolol and hydralazine have been well documented. Although the properties of beta blockers are not as strongly complementary to those of prazosin as they are to those of hydralazine their hypotensive effects summate with that of prazosin and the following synergistic interactions occur[4]: (1) the tendency for prazosin induced orthostatic tachycardia is countered by the negative chronotropic action of beta blockers (2) the blood pressure in the standing position tends to be higher than in the supine position with beta blockers but lower with prazosin (3) prazosin will prevent the predominance of unopposed alpha-constrictor vascular tone consequent upon blockade of the beta 2 receptor mediated vasodilator mechanism (4) beta blockers may prevent the provocation of angina pectoris by prazosin.

In the presence of adequate beta blockade the dose of prazosin may be increased to 30 mg/day and that of hydralazine to 200 mg/day (or higher in rapid acetylators with normal renal function). However such doses may not be well tolerated in patients who because of contraindications to beta blocker therapy were given one of the other sympatholytic agents at Step 2. Except in regard to the negative chronotropic effect of clonidine additive but not synergistic relationships exist between these agents and prazosin or hydrala-

Primary myocardial disease, diabetes mellitus and small vessel disease

In a recent comprehensive study on primary myocardial disease Shirey and associates included among their group of 133 patients with primary myocardial disease 12 patients with diabetes mellitus Based on biopsy findings—autopsies were performed in two diabetic patients only—the authors question the possible role of small vessel disease in the pathogenesis of diabetic heart disease An opposite view was taken by others and by us Fearce and colleagues obtained myocardial specimens by ventricular septal biopsy in eight patients with maturity onset diabetes Coronary angiography performed in four patients was normal in two patients with angina probably normal in one patient with congestive heart failure and with diffuse disease in one patient with cardiomegaly Focal myocardial fibrosis and varying degree of intimal proliferation of small vessels (30 to 100 microns) were present in all patients The negative results reported by Shirey and associates may be due to technical difficulties or to the imperfection of the technique Even the authors felt that it seems difficult to derive from biopsies the prevalence and significance of small vessel disease Biopsy technique missed focal changes of the myocardium in 33 of 133 patients (25%) The sample obtained by needle biopsy may or may not be representative of the whole Therefore autopsy remains the best method in evaluating the changes taking place in the myocardium We obtained parafin blocks of 87 hearts from 50 diabetic nonhypertensive patients, and from 37 nondiabetic patients Four blocks were taken from seven areas Each block was sectioned at 6 microns and four sections were stained with hematoxylin-eosin and Verhoeff Van-Gieson stain Small coronary artery involvement (20 to 150 microns) found in 36 diabetic patients (72%) consisted of (1) endothelial proliferation (2) subendothelial fibrosis (3) exudative deposits of hyaline in the intima and (4) atheromatous thickening with cholesterol clefts and hyalinized intima Intramural vessel involvement alone was found in 18 patients (36%) The heart was enlarged—over 400 g males, and over 35 females in eight patients with small artery involvement and normal extramural coronary arteries In the control group of 32 nondiabetic patients involvement of the intramural arteries only was detected in four cases Since the control group presented a variety of clinical manifestations there is the possibility that intramural vessel involvement was the consequence of underlying clinical disease The small artery changes are not specific for diabetes mellitus, but they

When is loss of responsiveness to a vasodilator agent in the patient with congestive heart failure due to tachyphylaxis?

One of the subjects of important debate at the recent meetings in Anaheim involved vasodilator therapy for advanced congestive heart failure Almost 30 years ago dibenamine was shown to decrease right atrial and pulmonary pressure in patients with congestive heart failure and patients with acute pulmonary congestion and edema refractory to conventional therapy were then reported to respond dramatically to the administration of adrenergic or ganglionic blocking agents Burch and colleagues pointed out that the salutary response in this situation was much more likely to reflect venous dilatation than afterload reduction There is continued broad agreement that a beneficial response occurs with the acute administration of a number of additional agents. With attempts at chronic therapy debate now centers on how well sustained responses to individual agents are a recurrent theme appears to be that agents lose their effectiveness with time Unfortunately the term tachyphylaxis has been employed by some to describe this loss of responsiveness in patients with heart failure providing a contemporary example of how the misuse of word can confuse issues

When should we employ the term tachyphylaxis rather than the more humble terms refractory resistant or unresponsive? What additional information does this complicated word carry if any? If it is merely a synonym for refractory or unresponsive we clearly should not use it

As used in pharmacology tachyphylaxis connotes an element of specificity which unresponsiveness does not Vascular smooth muscle for example may fail to dilate in response to an agent because the reduced blood flow is not due to active vasoconstriction but rather to some mechanical problem such as edema of the vessel wall an alteration in excitation-contraction coupling or the contractile apparatus itself so that vasodilatation is not possible In these cases the refractory state would be generalized and no agent would induce a response Alternatively response to a specific agent might be lost because of a change in the number or affinity of the available receptors for that agent or because a change in the physiology of the milieu makes the agent ineffective An excellent example of the latter phenomenon was provided by the studies of Watkins and associates. When acute CHF was induced in the dog converting enzyme inhibition reduced blood pressure strikingly Over the next several days arterial blood pressure and by inference afterload no longer responded to the inhibition Plasma renin activity rose sharply following the acute onset of CHF and gradually returned to control value as sodium retention occurred accounting for the resistance of blood pressure to the inhibitor A similar sequence could well account for the loss of effectiveness of alpha adrenergic blocking agents. In this case the loss of responsiveness would be specific for a single agent and the system would be capable of responding to other agents. The term tachyphylaxis should be applied to this specific case in which responsiveness is lost to only one agent thus discriminating the loss of response from a generalized refractory state

This distinction clearly would have important implications for pathophysiology and therapy Until alternative agents have been assessed and have been shown to be ineffective the term tachyphylaxis should not be applied. One cannot help but wonder how much of the debate would be resolved if we knew whether patients who apparently become resistant to prazosin or hydralazine have indeed become resistant to all agents Does resistance to one agent preclude effective use of another? Anecdotal, clinical experience indicates that this is not so but none of the formal studies have attempted to answer this important question

The notion of course applies to other therapeutic maneuvers Investigators and clinicians involved in the treatment of problems as diverse as cardiac arrythmia hypertension recurrent urinary tract infections, and leukemias often face the problem of the patient whose condition has become refractory to a specific agent—fortunately most have resisted the temptation to replace the general term with tachyphylaxis

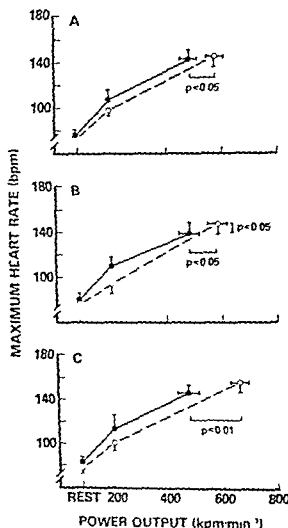

Fig 1 Mean (± SEM) maximal heart rate and power output changes over (A) 0 to 7 months (n = 17) (B) 0 to 12 months (n = 1) and (C) 0 to 21 months (n = 7)

for at least 7 months. 10 patients continued in the program for 12 months, and continued for 21 months. Their mean age (x ± 1 SD) was 2 6 ± 8 4 years 13 had suffered a myocardial infarction three of whom subsequently had bypass surgery. Two patients had undergone bypass surgery without a prior infarction and two had angina pectoris without infarction or bypass. Exercise testing was carried out on a calibrated electrically stabilized load-cycle ergometer on entry and 7 12, and 21 months later changes in heart rate systolic blood pressure rate pressure product expired ventilation and power output were analyzed over 0 to 7 0 to 12, and 0 to 21 months. The exercise program consisted of 30 to 40 minutes of treadmill walking and cycle ergometry and 20 to 30 minutes of volleyball. The patients met twice weekly and were expected to exercise at home on at least two other days. The intensity of exercise was prescribed by the method of Balke supervision was provided by two exercise leaders and a physician

Following regular participation in the program for as long as 21 months, there were no changes in weigh resting heart rate but significant ($p < 0.05$) increases were observed in resting systolic blood pressure and rate pressure product by 12 and 21 months. No significant changes were observed in the cardiorespiratory responses at a constant submaximal power output (200 kpm min.⁻¹) at any time, although heart rate at 200 kpm min⁻¹ was lower at each test (0 to 7 months = 9 bpm, 0 to 12 months = −15 bpm 0 to 21 months = −12 bpm. Significantly higher maximum power outputs (x ± 1 SE) were observed (Fig 1) at the end of 7 months participation (489 ± 31 to 579 ± 33 kpm min.⁻¹) over 12 months (ff to 575 ± 39 kpm min) and over 21 months ((to 6?1 ± 28 kpm min) Maximum heart rate (x ± 1 SE) increased over each period but significantly only over the 0 to 12 months period (138 ± 9 to 14 ± 8 bpm) there were no significant changes in maximal systolic blood pressure rate-pressure product or expired ventilation at any time

The proportions of females and males referred to the exercise rehabilitation program were similar to those reported for other programs in North America and presumably reflect the lower incidence of coronary heart disease in females and perhaps a smaller number of exercising North American middle aged females than males. The dropout rate was somewhat higher than that observed in male cardiac patients exercising at the same institution. The increase in maximal power output and maximal heart rate was similar to that observed in male cardiac patients. The submaximal responses during progressive exercise testing, although not statistically significant, were similar to those reported in the literature for male cardiac patients the decrease in similar to that observed in 190 male cardiac patients at the institution who within 6 months, demonstrated a significant (p < 0.05) decrease of 12% in submaximal heart rate with a similar exercise prescription (N Oldridge unpublished data). All 17 patients claimed that they were able to carry activities of daily living with greater self assurance and fewer problems than before entering the program. This qualitative subjective improvement in their daily life should be considered at least as important an effect of training as a quantitative improvement found during submaximal work or in maximal power output. These observations suggest that physical conditioning plays as important a role in the rehabilitation of selected female coronary heart disease patients as it does in male patients, particularly in their ability to carry out activities of daily living with a renewed sense of confidence

frequency and severity in this disease make them a highly characteristic feature The small stiff heart causing onset of acute pulmonary edema was reported in diabetic patients when both intramural and extramural coronary arteries were severely involved Functional derangements in the microcirculation of diabetic patients as a result of small vessel involvement might represent one of the basic causes of myocardial impairment and conduction disturbances.

The changes taking place in the myocardial circulation and metabolic abnormalities, including deposits of PAS material in the left ventricular interstitium might determine progression of the process A basic departure from the concept—that the myocardial microcirculation in diabetics is different from all the other organs—is taking place Recently there have been reports describing thickening and proliferation of the capillary basement membrane as a generalized phenomena taking place in many organs including the heart For the first time *diabetic capillary microaneurysms have been observed* in the hearts of three of six diabetic patients

A protracted period of controversy seems to be approaching its end The intramural circulation may ultimately be recognized as an important factor in the pathogenesis of diabetic heart disease

Exercise rehabilitation of female patients with coronary heart disease

Cardiorespiratory responses to physical conditioning have been extensively studied in male coronary heart disease patients but little information is available for female cardiac patients undergoing similar programs Twenty eight female cardiac patients were referred to a supervised exercise rehabilitation program between March 1973 and March 1977 (approximately 8% of male patient referrals over the same time period) 17 of these patients participated in the program

hyperplasia presumably resulting from vasoconstriction has been the basis for vasodilator therapy for primary pulmonary hypertension Early reports demonstrated pulmonary vasodilatation in pulmonary hypertensive patients who received intravenous infusions of isoproterenol or tolazoline but systemic side effects are common and the clinical usefulness of this therapeutic approach is limited Only a handful of patients have been reported to obtain benefit from sublingual isoproterenol [1] and the duration of action after each dose is short Furthermore the absence of any long term follow up of patients treated in this manner speaks of its not being of lasting help over the long haul Nevertheless the demonstration that the hypertensive pulmonary arterial bed can dilate in response to the administration of vasodilators was encouraging and it initiated a search for more effective and better tolerated pulmonary vasodilators

Diazoxide a potent systemic antihypertensive agent has recently been demonstrated to be a pulmonary vasodilator in four patients with primary pulmonary hypertension In two separate reports diazoxide given intravenously caused a reduction in pulmonary arteriolar resistance and an increased cardiac output without affecting systemic blood pressure Surprisingly the drug was also effective when administered orally and hemodynamic and symptomatic improvement persisted in the patients who were maintained on chronic oral therapy This drug however is not given without hazard a death was recently reported after intrapulmonary diazoxide was given to a patient with primary pulmonary hypertension

In a recent case report a pati[illegible]nt with primary pulmonary hypertension evidenc[illegible] h[illegible]m[illegible]dynamic improvement with the intravenous injecti[illegible]n [illegible] phentolamine an α adrenergic inhibitor This patient [illegible] eated with oral phentolamine and on repeat catheter[illegible] seven months later a persistent response wa[illegible] d[illegible] [illegible]rente[illegible]

We recently re[illegible]p[illegible]rted our experience using oral hydralazine in four patients with primary pulmonary hypertension In those patients the administration of hydralazine 50 mg by mouth every six hours for 48 hours resulted in a reduction in pulmonary arteriolar resistance and an increase in cardiac ou[illegible]put at rest Similar changes were also observed in three patients who were also studied during a period of exercise on a bicycle ergometer Repeat cardiac catheterizations were performed four to six months after beginning chronic oral hydralazine therapy and the hemodynamic improvement persisted Our patients also had symptomatic improvement and this dose of hydralazine was tolerated without significant side effects Since the publication of our original experience we have had the opportunity to study three additional patients with this disease two of these had responses comparable to those in our original series

Despite the inherent risks it is our current practice to perform right heart catheterization before and after instituting hydralazine therapy on all patients who are referred to us with the diagnosis of primary pulmonary hypertension We have tested our patients for pulmonary vascular responsiveness to the administration of 100% oxygen (seven patients) and intravenous phentolamine (four patients) but we have not found either modality useful

The temptation to empirically treat pulmonary hypertensive patients with vasodilators must be strongly resisted Hemodynamic changes may be the only evidence of improvement It is clear that not all patients will respond to this therapeutic approach and no drug should be given to a patient without the demonstration of both its indication and its efficacy Systemic hypotension could prove fatal to these often hemodynamically fragile patients Furthermore vasodilator therapy could augment the right-to-left intracardiac shunting in patients with pulmonary hypertension resulting from an unsuspected patent foramen ovale and these drugs should be used cautiously in this setting.

The demonstration that oral vasodilator therapy can lead to hemodynamic improvement in some patients with primary pulmonary hypertension has raised several important questions

1 Which vasodilator is the safest and most effective for pulmonary hypertension?

2 What is the optimal dose of a vasodilator for patients with primary pulmonary hypertension? It is now well known that there is a marked variability in the dose requirements of vasodilators for left ventricular failure and undoubtedly a comparable situation exists in pulmonary hypertension

3 What is the role of concomitant anticoagulant therapy for primary pulmonary hypertension? Although anticoagulation does not appear to cause hemodynamic or symptomatic improvement the increased risk of thromboembolic disease in this setting may be a justification for anticoagulant therapy Our practice however is currently to withhold anticoagulation unless a clear indication is present.

4 Can the response to vasodilator therapy yield insight into the pathogenesis of this disease? Clarification of the mechanisms of pulmonary vasodilation could not only lead to the discovery of more effective pulmonary vasodilators but it could also provide information concerning the mechanisms of vasoconstriction in the abnormal pulmonary vascular bed

The answers to these questions will undoubtedly lead to newer approaches to the treatment of this tragic disease

Of the Q wave and myocardial infarction

There is an erroneous tendency to assume that only a Q wave abnormality is necessary to establish electrocardiographic diagnosis of myocardial infarction Thus some clinicians consider that unless a Q wave of infarction is present myocardial infarction does not exist Nothing could be further from the truth than that concept Those who subscribe to this concept and so frequently include it in their publications fail to realize that the time course of the Q wave occurs early in the depolarization process of the ventricles Therefore only infarction in the myocardial area depolarized early in the activation of the electric cycle can be expected to display abnormal Q waves in the ECG But the QRS complex continues on beyond the Q wave time in the time course of the entire depolarization process Therefore what about infarcts in the areas of the ventricle which are depolarized late and last durin the depolarization process? How could these infarcts change the early portions of the QRS complex or produce or change the Q wave? Obviously they don t Only the late or later parts of the QRS complex are abnormal when infarction occurs in myocardial areas depolarized late in the activation process This has been clearly shown and reported a number of years ago Therefore the lack of Q wave abnormalities does not exclude ECG evidence of myocardial infarction involving those parts of the ventricle depolarized late or last The absence of a Q wave abnormality only excludes evidence for infarction of areas of the ventricular myocardium depolarized early Furthermore it should be remembered that infarction of portions of the myocardium depolarized early may produce abnormalities of the early portions of the QRS complex other than the development of Q waves.

Primary pulmonary hypertension new approaches to therapy

Thirty years after its original clinical description primary pulmonary hypertension remains a disease of unknown cause and the few clues to its pathogenesis have not generally led to useful therapeutic modalities. The association of pulmonary hypertension with connective tissue diseases suggests an immunologic or inflammatory process but corticosteroids and cytotoxic drugs have no effect on the course of this disease Some investigators have postulated that microemboli possibly resulting from a hereditary defect in fibrinolysis cause the extreme elevations in pulmonary arterial pressures which are often seen in patients with this disease but anticoagulant therapy has not met with success. The exacerbation of pulmonary hypertension during pregnancy and the association of pulmonary hypertension with portal hypertension have led some observers to believe that the disease is the result of a hormonal abnormality To date however no specific defect has been demonstrated

washings. While hepatitis B has been transmitted to non human primates by subcutaneous or intravenous injection of HBs Ag positive saliva [illegible] intranasal and intra-oral installation did not result in infection. The possibility of HBs Ag in saliva reaching the blood of a mouth to mouth operator through small mucosal cracks is suggested by the report of transmission of hepatitis B by a human bite. Although the transmission of hepatitis B after mouth to-mouth contact of a person with a patient carrying HBs Ag in his blood or saliva has not been reported it would seem prudent to provide mouth to-mouth contacts of HBs Ag positive individuals with the same prophylaxis offered to those exposed to hepatitis B through inadvertent needle puncture from patients known to be HBs Ag positive. Such prophylaxis consists of [illegible] hepatitis B immune globulin given intramuscularly in a dose of 0.5 mL/kg body weight administered as soon as possible and repeated in [illegible] days.

Concern has also been expressed about the risk of transmitting hepatitis B via HBs Ag positive saliva that has contaminated the mannequins used to train individuals in CPR. Osterholm and colleagues studied 22 individuals who had participated in a CPR training programme. One of the students developed hepatitis B eight days later and carried HBs Ag in his blood and saliva but none of the contacts acquired hepatitis B. There was also no transmission of hepatitis to 23 individuals after mouth to-mouth contact with a CPR mannequin used by the instructor who subsequently developed hepatitis non A, non B. Another fortuitous experiment was the exposure of 12 students to HBs Ag positive saliva via contact with contaminated musical instruments. Although the instruments were not cleaned between use by the students and the HBs Ag [illegible] no transmission of hepatitis B [illegible] R training mannequins have not been [illegible] transmission of hepatitis B [illegible] mannequin's oral surface be clea[illegible] and that the manne[illegible] cleaned after each training [illegible]

[illegible] be transmitted from person to [illegible] the upper respiratory tract [illegible] pharyngeal secretions of persons [illegible] Although the paucity of reported [illegible] of meningococcal infection by mouth [illegible] that the risk of such transmission [illegible] mouth to-mouth contacts is heightened because [illegible] infection may be rapidly fatal. Jacobson and Fraser recommended that mouth to-mouth contacts of patients with meningococcal infection be given the same chemoprophylaxis with rifampicin, sulfadiazine or minocycline as other close contacts. However there may be a very brief period of colonization of the upper respiratory tract before the onset of meningococcal infection. To eradicate a potential [illegible] bacteremia in the mouth to-mouth contact Artenstein recommended procaine penicillin intramuscular [illegible] 500 000 units three times daily for two days, followed by orally administered penicillin V 500 mg three times daily for eight days. However Artenstein's regimen may be ineffective because meningococcal infection has been reported in close but not mouth to-mouth contacts receiving intramuscular procaine penicillin and benzathine penicillin for chemoprophylaxis. When faced with this dilemma I have recommended that the mouth to-mouth operator be admitted to hospital and started on 12 million units of penicillin intravenously in divided doses over [illegible] hours after [illegible] has been drawn for culture. The mouth to-mouth operator is discharged two days later if no symptoms develop and the cultures are sterile. Although this approach may seem overzealous, my experience has been that [illegible] the mouth to-mouth operator allays much of the [illegible] usually engendered by the exposure to a patient with meningococcal infection.

The seemingly very small risk of transmission of [illegible] from patient to operator during mouth to-mouth resuscitation is no reason to abandon mouth to-mouth resuscitation. However more frequent documentation of the [illegible] of such contacts with patients harboring various [illegible] would allow a better appreciation of the risk involved.

of viral nephritis

is still doubt in the minds of many physicians and even me nephrologists as to whether or not virus will infect dneys. Viral nephritis due to the Coxsackie B virus has been ed However it is well known that renal tissue ides a good culture medium for the picornaviruses The o virus is grown on kidney tissue culture and this is rtainly true for other viruses of this same group namely the kie viruses. This is proof enough that at least the infect renal cells.

- hazards of mouth to mouth

ai

lthough it has been suggested that a fear of transmission of ection delayed the widespread acceptance of mouth to-outh breathing in the late 1940s scant attention is current given to the risks of transmitting infection from patient to rator during mouth to-mouth resuscitation The encour ement of prompt cardiopulmonary resuscitation (CPR) by th lay people and paramedical personnel in the community ll surely result in increasing numbers being exposed to oro-aryngeal secretions of patients who may be harboring an Cutaneous tuberculosis and meningococca infec n have been described in operators of mouth to mouth iscitation of patients with these diseases One can only ulate about the potential for transmission of other micro- during mouth to mouth resuscitation The risks of smitting hepatitis and meningococcal infection deserve special attention not only because of the potentially serious consequences of the infection but also because the management of such mouth to mouth contacts is debatable

Oropharyngeal secretions are not an important source for transmission of hepatitis A virus while hepatitis B is most likely to be transmitted by the parenteral route via blood blood products or blood drawing equipment However the mouth to-mouth route of transmission of hepatitis B is theoretically possible by two mechanisms

1 Hepatitis B has been transmitted to children by the oral administration of as little as 0 5 mL of hepatitis B surface antigen (HBs Ag) positive serum Thus bleeding about the oropharynx of the patient may result in blood containing HBs Ag being swallowed by the mouth to-mouth operator

2. HBs Ag may be found in both aliva and nasophar-

increased incidence of prematurity (22% one third of whom died) and stillbirth (13%) While liveborn morbidity was much less fetal or neonatal death was substantially greater with heparin use than with coumarin derivative exposure In addition maternal risk *may* be greater with heparin use (at least as previously administered)

Both of these agents carry substantial risks when used in pregnancy Because of this preconceptual counseling and if pregnancy occurs offering the option of therapeutic abortion appear to be the most prudent If anticoagulation and continuation of pregnancy are necessary the clinician is left to choose between unattractive alternatives Continued experience may demonstrate that heparin is in fact safer than our retrospective review would indicate For the present however coumarin derivatives remain a reasonable alternative if the *relative risks are explained carefully to the prospective parents*

of anticoagulation during pregnancy

he recognition that coumarin derivative oral anticoagulants have adverse effects on the fetus has followed a tortuous h. The increased sensitivity of off pring to the hemorrhagic of the active principle of damaged sweet clover wa served more than 50 years ago and hemorrhagic compli a in human newborns resulted in general recommenda that these agents (including Coumadin [Endo Laborato] shouldn t be used in the latter part of the third trimester pregnancy

n the last five years we and others have demonstrated coumarin derivative exposure in the first trimester of results in a specific malformation syndrome in infants which has come to be known as the warfarin bryopathy We are aware of 39 infants with the warfarin nbryopathy which is characterized by nasal hypoplasia and ippled epiphyses Review of exposure histories in these ca es cates that there is a critical period of exposure between six d nine weeks of gestation that can result in the appearance the warfarin embryopathy The severity of this syndrome is riable follow up studies indicate that while seven subjects ve died most survivors have a relatively good outlook with lf having no severe disability at all.

Our recent review also summarizes experience with central rvous system effects of coumarin derivative exposure in ero Administration of these agents in the second and third mester appears to be associated with deformation of the ntral nervous system resulting in mental retardation and/ blindness A total of 15 such cases were found While some ildren have had both the embryopathy and central nervous stem abnormalities these appear to be two independent ocesses with different sensitive periods during gestation fferent mechanisms of pathogenesis and with independent additive risks

So coumarin derivative exposure in the sixth to ninth weeks the first trimester carries some risk for the warfarin ryopathy exposure in the second and/or third trimesters with increased incidence of central nervous stem abnormalities and late third trimester exposure carries with it a clearly recognized danger of late prenatal, perinatal or postnatal hemorrhage

Nevertheless use of anticoagulants during pregnancy may be necessary because of maternal thrombophlebitis with embolization or maternal prosthetic heart valves. Counseling of such women requires estimation of the involved risks The most satisfactory approach would be a prospective controlled trial but no such trial has been undertaken and since the coumarin derivatives are now contraindicated during pregnancy by their manufacturers none will probably be forthcoming Yet some estimate needs to be available After an unsuccessful attempt to retrospectively ascertain all women given anticoagulants during pregnancy in the Seattle Washington area over the past ten years, we chose to review the world s literature from 1945 through 19 8 attempting to find all published cases of courmarin derivative (and for comparison heparin) use during pregnancy The limitations and bias of such a study should be evident therefore our risk figures must be considered as *estimates* For coumarin derivatives 418 literature cases were reviewed Over all only two thirds of these pregnancies resulted in reasonably normal fetal outcome Abnormalities in the others were primarily secondary to hemorrhage warfarin embryopathy central nervous system effects and spontaneous abortion. In at risk pregnancies (exposure between six and nine week of gestation) about 8% of infants were reported to have features of the embryopathy The over all risk of central nervous system effects appears to be about 3% Of liveborn infants 16% had some significant sequelae So the best available estimates indicate that with coumarin derivative use one sixth of pregnancies will result in abnormal liveborn infants, one-sixth will end in abortion or stillbirth and about two-thirds will have a relatively normal outcome

Data from 135 published cases in which heparin was used during pregnancy indicate a virtually identical complication rate less than two-thirds of such pregnancies resulted in normal children The kinds of problems, however were quite different heparin use was associated for the most part with

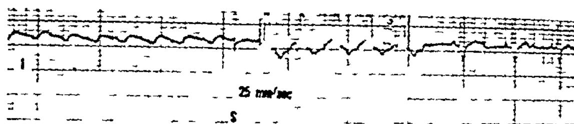

Fig 1 Ventricular tachycardia with a rate of 140 per minute terminated after six ventricular stimulations at a rate of 110 per minute

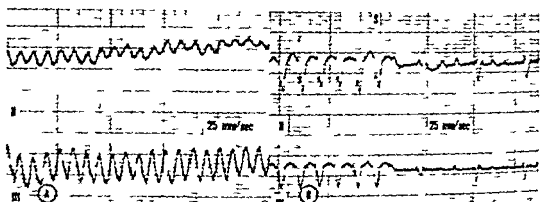

Fig 2 Simultaneous recording of Leads II and III A ventricular flutter with a rate of 260 per minute B ventricular stimulation at 200 stimuli per minute and then sinus rhythm with A V block.

interrupted the reentry circuit, allowing the others to drive the atrium, and after the last stimulus sinus rhythm occurred.

The same mechanism was observed in a 70-year-old woman with total A V block and bursts of ventricular tachycardia and ventricular flutter uninfluenced by repeated DC shocks. The ventricular stimulation below the rate of ventricular tachycardia (Fig 1) and below the rate of ventricular flutter (Fig 2) succeeded in driving the ventricles and finally in stopping the arrhythmia A permanent ventricular pacemaker was effective in preventing these arrhythmias and the patient was in satisfactory condition at a follow up examination 3 months later

TTM versus Holter monitoring of symptomatic arrhythmias

To the Editor

In their article in the October 1979 issue of the Journ (AM HEART J 98 459 1979) Dr R S Grodman and as ciates pointed out that the value of a patient activated EC telephonic transmission system (TTM) was statistically s

ic electrocardiographic recording ring sexual activity in recent post myocardial and revascularization patients

the Editor

We greatly appreciated the article of Johnston and Fletcher hich appeared in the December 1979 issue of the AMERICAN HEART JOURNAL, and we would like to make some comment it.

At the moment in our Cardiac Rehabilitation Center we focused our attention only on post myocardial infarction atients (post MI Pts)

Sixty nine post MI Pts, 26 randomly assigned to a physical 27 to a control group and 16 excluded randomization for cardiovascular contraindications, per 85 24 hour ambulatory electrocardiograms during hich there were 86 occurrences of sexual intercourse

The time lapse from MI was 49 6 ± 10.3 days, ages, ranged 30 to 64 years (x̄ = 49) the infarction was inferoposterior 41 and anterior in 28 patients.

Total time for sexual activity ranged from 8 to 28 minutes = 16.5) and we included in the analysis 10 minutes before 10 minutes *after that event peak heart rate ranged from* 170 beats per minute (x̄ = 106)

Ventricular ectopic activity (VEA) was graded according to Lown system integrated with a study of bi tri and and has been expressed as percent of hours certain degree of VEA. A total of 1 092 daily hours 86 instances of sexual intercourse have been reviewed eeping hours have not been included. Total VEA and ultiform extrasystoles were increased although not signifi during sexual activity (SA) The most striking differ regarded the advanced grades of VEA, namely couplets, and bi, tri and quadrigeminy that all significantly more frequent during SA ($P < 0.025$)

A further analysis comparing sex with other daily activities as driving, climbing stairs, light manual work, prandial post prandial state awakening etc., showed that though SA elicited more advanced grades of VEA the fference was not statistically significant.

In our total population of 263 patients under study we have ot observed any "mort d amour" In conclusion, in our xperience sexual activity in the early post hospital phase of II is not clearly a stronger stimulus than are other activities r cardiac electric instability Even if we agree that appro counseling should obviously be expressed regarding ivity in this phase of patient management excessive seems to be inappropriate and may create psycholog problems.

To the Editor

We appreciate the interest shown in our study by Drs. Paolillo and associates. It appears as though both groups of data are quite comparable However Paolillo and co-workers studied only patients with myocardial infarction and at a time of *49 6* days post infarction Our myocardial infarction patients were monitored at an *earlier* mean time of *30 1* days post infarction This earlier "time frame" for monitoring *could possibly account for the fact that one myocardial* infarction patient experienced ventricular bigeminy and ventricular coupling during sexual activity and not during other activities within his 24 hours. However the higher grades of ventricular ectopic activity (VEA) detected by Paolillo and colleagues, even at a later time post myocardial infarction, should be of concern We concur that counseling should not be such as to incite "alarm" in the patient and partner However the apparent relationship between the incidence of sudden death and high grade VEA in patients with ischemic heart disease does warrant consideration of therapeutic approaches that are tailored for the benefit of the individual subject in question.

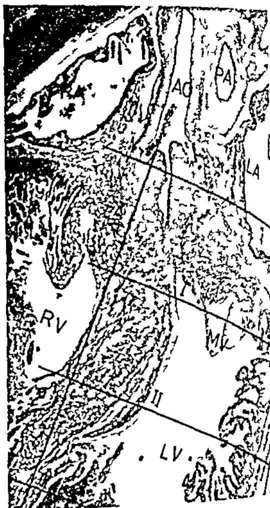
Ratios of septum and LV free wall in IHSS and HCM

To the Editor

Idiopathic hypertrophic subaortic stenosis or hypertrophic cardiomyopathy is characterized by asymmetric septal hypertrophy (ASH) myocardial fiber disarray and often systolic anterior motion of the mitral valve (SAM) Although these findings are highly suggestive however none of them are pathognomonic for this fascinating disorder ASH (a ratio of the septum to posterior left ventricular free wall of ≥ 1 3) has been reported in normal embryonic and newborn hearts as well as in certain congenital heart disorders While studying embryonic chicken hearts for a teratologic project we conducted a (quantitative) morphometric investigation on three groups of white Leghorn chicken hearts (8 day old embryos 1-day old chickens and adult specimens) Serial sections parallel to the frontal plane were obtained from 10 hearts in each group and were stained with hematoxylin and eosin Sections containing the ventricular septum medial leaflet of the mitral valve and the aortic root were used for morphometric study (Fig 1) A line *(A)* was drawn parallel to the longitudinal axis of the ventricular septum Perpendicular lines were dropped to line A at three points (dividing line A into four equal portions) and were extended laterally to cross the left ventricular free wall The length of the line A was determined by the aortic root *(Y)* superiorly and its point of intersection (X) with line B passing tangentially to the



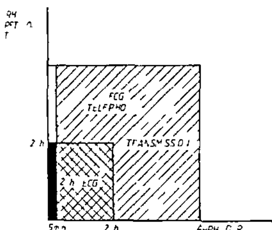


Fig 1 A typical frontal section of chicken heart contain[ing] the aortic root *(AO)* the medial cusp of the mitral val[ve] *(MV)* and lines drawn for measuring septal to left ventricu[lar] wall thickness ratio at three equidistant levels *(I II* and *III)* Line B is not shown in the Figure *LA* = left atriu[m] *LV* = left ventricle *PA* = pulmonary artery *RA* r[ight] atrium *RV* = right ventricle

lowermost part of the left ventricular wall. Ratios of t[he] septal thickness to the left ventricular wall were measured [at] three levels for the three groups and were compared using [t]... hypothesis on mean ± SD of each group (Table I) The st[atistical analysis] showed that

1 The ratio for the upper portion *(level I)* of the septum [to] left ventricular free wall is quite large in the embryonic [heart] and this ratio is rapidly reduced so that in 1-day-old chick[ens] the upper ratio has reached the adult level and does [not] change further with advancing age

2 The ratio for the middle portion *(level II)* declines [more] gradually so that in 1 day old chickens it is not signific[antly] less than in the 8-day-old embryos however as the chick[ens] mature this ratio is gradually reduced and becomes sig[nifi]cantly smaller in the adult specimens.

3 The ratio for the lower portion *(level III)* though redu[ced] with advancing age is not significantly different among [the] three groups

g 1 Diagram illustrating the overlapping coverage of mptomatic arrhythmias provided by the use of *both* TTM nd 24 hour Holter monitoring Short lasting symptomatic rrhythmias (< 5 min i e mean TTM-connection time) of igh reoccurrence frequency (> one phenomenon/day) could nly be captured using HT *(pure black field)* whereas rare rrhythmias (< 1/day) will remain undiscovered in spite of ne aplication of both methods used *(pure white field)*

ificantly higher (χ = 3 69 p < 0 05) than the analysis of one 4 hour Holter tape (HT)

But the truth is that each method brings different strengths o the problem of capturing symptomatic arrhythmias

It is important to understand that the sensitivity of HT and M depends on the frequency of the occurrence of symptoms vs. arrhythmias In 9? symptomatic patients—in spite of mean 4 days (maximum 21 days) continuous monitoring ime under ambulatory conditions—a symptom/ECG correla ion could be achieved in only 40 patients Using computer upported HT analysis sytems the analysis of synchronous egistration of ECG and symptoms leads to the true result ndependent of the duration of the phenomenon

On the other hand a successful application of TTM (i.e a imultaneous ECG registration of a symptomatic period) resupposes that there will be a telephone connection between he patient and the receiving unit *before* the symptoms anish.

So we conclude that the value of HT analysis depends on he *frequency* whereas the value of TTM is a function of the *duration* of symptoms vs arrhythmias A disregard of the luration and frequency of symptoms shows a lack of under tanding of the value of each method

Both methods are useful tools with which to reduce the white field (see Fig 1) of undiscovered symptomatic arrhyth mias by the use of overlapping data

To the Editor

We thank Drs Weber Steinbach, Joskowicz, Glogar and Kaindl for their interest in our article We agreed that the sensitivity of Holter monitoring (H.M) and transtelephonic monitoring (T T M) is a function of the frequency and duration of symptoms and arrhythmias.

The efficacy of H M is truly limited by the frequency of the patient s symptoms it is less likely to document symptom related arrhythmias in the sporadic patient than in the highly ymptomatic patient. This is exactly the reason we sought to test T T M as an alternative to H.M in this situation. T T.M., on the other hand is duration limited i e. an arrhythmia must be present at the time of the transtelephonic transmission in order to be documented In addition a sustained critical arrhythmia may render the patient incapable of transtelephonic transmission thereby losing the opportunity for symptom ECG correlation We have recognized these conditions and listed them in our discussion as did Hasin and colleagues and Judson and co-workers in their studies on the usage of T T.M

We believe it is important when correlating symptoms with the transmitted ECG to have the patient relate by telephone whether or not symptoms were actually occurring *during* the period of ECG transmission This will eliminate one source of symptom ECG disparity Also by extending the time period for the use of T T M., it will be more likely that a truly symptomatic period can be recorded further improving the sensitivity of the method.

Weber and associates note that a period of continuous ECG ambulatory monitoring of 4 days (mean) duration, with a maximum continuous recording period of 21 days, can achieve a high incidence of recording during symptoms, and a high symptom ECG correlation This frequent application of continuous recording is appropriate for investigative purposes, but is neither practical nor possible in the routine care of patients. Thus effective therapeutic efforts must depend on either a single or perhaps two 24 hour Holter recordings or must seek other techniques for documentation of the patient s ECG at the time of potential cardiac symptoms. We believe that the T T.M has emerged as one method of achieving this goal

Finally we stated that T T.M both complements and supplements H.M in symptomatic patients. There still will

We note also that Case 2 was not described as having an abnormal mean frontal QRS axis on the electrocardiogram whereas five of the six patient described by Ehlers and associates had a superiorly orientated axis, and this has also been our experience (Duncan W J., unpublished observations) Is there any further evidence not mentioned in the article that might suggest that Case 2 does in fact have eccentric left ventricular hypertrophy rather than an aneurysm?

We appreciate the comments of Dr Burns and colleagues regarding Case No 2 in our recent communication Our Case No 2 did not demonstrate the electrocardiographic abnormalities seen by Ehlers and associates in patients with eccentric left ventricular hypertrophy The mean frontal QRS axis was +30 degrees and there was normal progression of the R wave in all precordial leads. Furthermore an echocardiogram obtained at the age of 13 years when the patient weighed 95 pounds demonstrated the thickness of the interventricular septum as well as the left ventricular posterior wall to be 8 mm. A chromosomal analysis has not been done but the patient has no abnormal features to suggest any syndrome Therefore we feel that this case demonstrates a left ventricular aneurysm rather than eccentric left ventricular hypertrophy of the left ventricule

Anomalous ECG and PCG recordings

To the Editor

In the article by Drs. Lofty L. Basta and Jerry J Ber... (AM HEART J 97 96 1979) on page 108, in Fig 13, the left parasternal cardiogram and the phonocardiogram seem to have some mistakes. If the figure is placed correctly points E in the parasternal cardiogram and S_1 in the phonocardiogram are labeled incorrectly because each of them precedes the QRS complex in the ECG On the other hand, the S_1-S_2 interval being longer than the S_2-S_1 interval is peculiar

I think that this figure should be placed upside down; then one could see the positive P wave with a P R interval of 0.2 sec. in the ECG the S_1-S_2 greater than S_2-S_1 and the form S_1 in the PCG and point E after the QRS and a large systolic positive outward movement in the parasternal cardiogram.

I would appreciate it very much if you could reevaluate this matter

However this particular recording is obtained from a patient with left bundle branch block and marked intraventricular conduction delay The initial part of the QRS is not seen in the ECG lead recorded. *In fact*, it was about 0.08 sec earlier than the first upward deflection seen in this particular lead Furthermore we believe S_1 in this figure is the tricuspid component of the first heart sound recorded in the left parasternal area whereas the S_2 is the aortic component of the second heart sound which is considerably delayed in this case because of *left bundle branch block*, accounting for the long S_1-S_2 interval.

Fig 1 Left ventricular angiogram in diastole of a patient with eccentric left ventricular hypertrophy

LV hypertrophy versus aneurysm?

To the Editor

We enjoyed the article "Congenital aneurysms of the left ventricle" by Dr Singh and associates and we have one important question to raise. In the angiograms shown by Dr Singh and colleagues, we agree that three of the four cases showed convincing aneurysms of the left ventricle With regard to Case 2 however we were struck by the resemblance of the left ventricular outline to that seen in eccentric left ventricular hypertrophy as described by Ehlers and coworkers. We also have seen this particularly in patients with Noonan s syndrome We include a diastolic frame from such a left ventricular angiogram (Fig 1) to show the similarities. In systole the apical segment did not contract paradoxically

We note also that Case 2 was not described as having an abnormal mean frontal QRS axis on the electrocardiogram whereas five of the six patient described by Ehlers and associates[2] had a superiorly orientated axis and this has also been our experience (Duncan W J., unpublished observations) Is there any further evidence not mentioned in the article that might suggest that Case 2 does in fact have eccentric left ventricular hypertrophy rather than an aneurysm?

rdiac Rehabilitation for the Practicing Phys cian Edited Lenore R Zohman M D and Albert A Kattus M D St uis 19 9 The C V Mosby Company 124 pages

This is a 1?4 pa e book on a subject which is relatively poLr in cardiology All physicians responsible for patients th heart disease are primarily responsible for rehabilita n of their patient This book reviews briefly the concepts in actice today The nine parts include general discussions ychological considerations, work and job rehabilitation and b placement exercise programs, risk factors sexual activity d other aspects of rehabilitation of patients with myocar al infarction The many contributors express their views early and effectively This is the second volume of a series of lumes under the editorship of Dr Zohman These papers re presented at a symposium held during March 19 ysicians in practice will find these discussions to be useful d interesting especially if they have never considered rdiac rehabilitation seriously The increasing interest in this bject makes this publication important It is practical and is rected at the busy practicing clinician with little time for udy

ercise Electrocardiography Practical Approach Edited by dward K Chung M D F.A.C.C Baltimore 1979 The illiams & Wilkins Company 354 pages Price $30 00

This book on exercise testing electrocardiography edited by r Chung and 13 contributors reviews exercise testing tech ques and principles The problems related to the use of ercise testing are discussed Indications contraindications erpretation of data values in screening for heart disease nd complications are among the subjects discussed B cause f the use of exercise testing physicians who use and rely on his procedure in clinical practice will find this book interest g and especially useful for physicians in training The lus rations are good and the presentations of bibliographies re helpful This is not a book in which to find a concise ri cal discussion of the need for exercise testing dangers alue and limitations of exercise testing Nevertheless the use nd practices at present are described The reader will have to ecide for himself as to the usefulness of the book to him

Venous & Arterial Thrombosis Edited by J Heinrich Joist I D Ph D and Laurence A Sherman M.D New York 979 Grune & Stratton Inc 373 pages Price $18 50

This is a new publication on an old important clinical roblem It represents a series of reports from a symposium eld on April 6 and 7 19/8 The contributions include among he many a pects of thrombosis pathogenesis diagnosis, ulmonary embolism prevention mechanism of action of eparin and coumadin role of thrombolytic therapy myocar ial infarction cerebrovascular occlusive disease use of radioi otopic detection and platelet suppressant therapy This ublication provides a good single source on the subject of hrombosis It includes current concepts and interests It is a useful book for clinicians surely for cardiologists

Advances in Microcirculation The Microcirculation in Diabetes Edited by E Davis with B M Altura and H Harders Basel 19 9 S Karger AG 15? pages Price $81 00

This is volume 8 of *Advances in Microcirculation* Changes n the small vessels in diabetes though known to exist for many years remain a great puzzle in medicine This impor ant publication of 15? pages is extremely interesting Among the subjects discussed are hemorrheology basal lamina in capillaries, mana ement of leg ischemia and vascular smooth muscle The discussions are concerned with pathogenesis pathology and clinical diagnosis and management The rela tionship of diabetes to the vascular lesions is discussed effectively This is another important and timely volume on the microcirculation

Current Cardiology vol 1 Edited by M Irene Ferrer M D Boston 1979 Houghton Mifflin Company 384 pages Price $30 00

This is *Volume 1* of *Current Cardiology* the series to be edited by Dr Ferrer The purpose of these annual volumes is to make available the chan es in cardiology to the practicing physician and cardiologi t as they occur ea h year The 1? chapters in this volume include a discussion of hypertension valvular heart disease coronary artery disease pediatric cardiology ventricular function arrhythmias pacemakers the cardiac cell echocardiography cardiac surgery cardiovas cular pathology and other subjects The presentations are too brief to be comprehensive enough to inform the reader adequately of the subjects selected for discussion Some of these problems selected are complex and currently there are differences of opinion concerning the mechanism and patho physiology in olved and they need future study This is well exemplified by the chapter on the use of vasodilators for CHF Starling s law of the heart the role of the peripheral circula tion and the nervous system is too extensive a field to discuss in about 11 pages This is also true for the broad field of cardiovascular pathology whi h is presented in less than 20 pages Regardless the discussions are interesting and present current views in cardiology These vie vs are discussed in a critical manner It is hoped in future volumes that either fewer subjects are selected for more thorough and critical review or that the subjects selected be more specific There is a need for critical evaluation and review and discussion for the read r of current practices and concepts in cardiology This is especially important for the reader who is less informed and trained and who needs a critical evaluation of current concepts and practices in cardiology

Hemodynamics and the Blood Vessel Wall Edited by William E Stehbens, M D., Sprin field Ill. 19/9 Charles C Thomas, Publisher 646 pages Price $68.50

This is an important book Hydraulic engineers have devel oped the fundamental principles of fluid flowing through rigid tubes, whereas blood vessels are not rigid and blood is a non Newtonian fluid The hydraulic principles governing the flow of blood through small and large blood vessels depend upon different factors related to the elasticity of the wall the distensibility of the vessels the changing tone and other complex factors These and many other hemodynamic and physiologic phenomena are discussed by the several contribu tors. Blood flow in vessels in association with certain disease states such as aortic stenosis, aneurysms A V shunts and arterio clerosis are discussed

Stehbens a pathologist has nicely related morphologic normal, and pathologic tates to hemodynamic phenomena The book is a good one which should interest pathologists and physiologists. It is unlikely that practicing physicians will appreciate the book fully There has been a need to describe in a single volume for the convenience of others the relationship of the physiologic and morphologic characteristics of hemody namic phenomena.

Fourth Annual National Symposium on Aging

The Fourth Annual National Symposium on Aging will be held on November 15 and 16 1980 at the Golden Gateway Holiday Inn San Francisco Devoted to a review of health care needs of the elderly sessions will center on a description of health care for older people and a review of the resources available Specific and prevalent problems in geriatric medicine will be examined such as the aging heart stroke and the older patient cancer and aging and depression and disengagement among the elderly Ultimately the recommendations of this symposium will be included in the 1981 White House Conference Fee for the symposium is $90 and AMA credit is available For further information contact Continuing Education in Health Sciences University of California San Francisco 24 Kirkham San Francisco Calif 94143 Telephone (415) 666 3904

Clinical Recognition and Management of Heart Disease 1981

The 24th Annual Scientific Session of the American Heart Association, Arizona Affiliate will be held on January 21 through 24 1981 at the University of Arizona Health Sciences Center Tucson The seminar is entitled "Clinical Recognition and Management of Heart Disease 1981 Visiting faculty will include Robert S Eliot M D., University of Nebraska Michael S Gordon M D Ph D F A C P University of Miami School of Medicine Donald C Harrison M D., Stanford University and Douglas P Zipes, M D., Indiana University Emphasis will be placed on bedside observation and auscultatory skills stressed through the use of the Cardiac Patient Simulator The lectures will deal with the management of cardiovascular problems with special reference to new pharmacologic approaches and modes of therapy Comprehensive audiovisual presentations are planned and the course has been structured to permit participants to explore areas of individual interest in depth.

For further information write Gordon A Ewy M D Professor of Medicine Course Co-Director Dept of Internal Medicine Section of Cardiology Health Sciences Center University of Arizona Tucson Ariz 85724

Society for Clinical Trials Symposium

A Combined Annual Scientific Sessions of the Society for Clinical Trials and the Eighth Annual Symposium for Coordinating Clinical Trials will be held May 11 through 13 1981 in San Francisco California Sessions will focus on the design organization management and analyses of clinical trials Abstracts must be received by January 1 1981 For further information write Christian R Klimt M D Secretary Society for Clinical Trials Inc 600 Wyndhurst Ave Baltimore Md 21210

Lucien Dautrebande Pathophysiology Prize–1982

The "Foundation de Physiopathologie Professeur Lucien Dautrebande" will hold its next competition for the Dautrebande Prize in 1982 and the award will be approximately 1 400 000 Belgian francs. The award will be given for a work in human or animal clinical physiopathology preferably having therapeutic implications. For further information about the competition please write Office Fondation de Physiopathologie Professeur Lucien Dautrebande 35 chaussée de Liège 5200 Huy Belgium For consideration in the 1982 competition all papers must be received *before* December 31 1981.

Second Banff Hypoxia Symposium

The Second Banff Hypoxia Symposium sponsored by The Arctic Institute of North America will be held at the Banff Springs Hotel, Banff Alberta Canada on January 13 through 17 1981 The program is designed to interest clinicians and research workers a special session on January 17 will be devoted to the diagnosis management and prevention of altitude illness Registration for the four-day symposium is $150 or $120 if paid by December 1 1980 A maximum of [illegible] persons will be accepted For further information contact John R Sutton M D The Arctic Institute of North America The University of Calgary 2500 University Drive NW The University of Calgary Calgary Alberta Canada T2N 1N4 Telephone [illegible] 3387

Conference on Coronary Artery Bypass Surgery

The National Heart Lung and Blood Institute (NHLBI) in collaboration with the Office for Medical Applications of Research (OMAR) National Institutes of Health, and the National Center for Health Care Technology (NCHCT) are sponsoring a Consensus Development Conference on Coronary Artery Bypass Surgery to be held on December 3 through 5 1980 at the National Institutes of Health Bethesda Md. The conference will focus on the clinical and scientific aspects of coronary artery bypass surgery A second conference emphasizing the economic societal and ethical aspects of the procedure will be sponsored in Spring 1981 by the NCHCT with the collaboration of NHLBI and OMAR For further information regarding the December conference contact Nancie McManus, Prospect Associates, 11325 Seven Locks Rd., Potomac MD 20854 Telephone (301) 983-[illegible]

plete medical inventory including cardiac evaluation prior to pregnancy To start a pregnancy and then learn later that a serious illness such as cardiac disease exists only introduces problems which could have been prevented A satisfactory medical inventory can be obtained by a general or family physician or internist A cardiologist may be consulted if necessary Since any qualified cardiologist must be an equally qualified internist he can study the patient initially in close cooperation with the physician who is responsible for the obstetrics Should illness be found which would increase the risk of pregnancy then the findings should be clearly explained and discussed with the patient and her husband These discussions should involve the family physician and cardiologist if the cardiologist has been engaged in consideration Most congenital heart disease advanced valvular heart disease and large hearts (especially in the presence of congestive heart failure) are contraindications for pregnancy The patient should be the only one who can decide to have a pregnancy in spite of risks She should then be advised that close clinical surveillance and cardiac management will be necessary throughout the pregnancy and especially near and at the time of delivery

Patients should also be reminded that having a baby is relatively simple whereas rearing one is strenuous ever demanding and a never ending problem even for normal people Patients with relatively mild heart disease at the time of pregnancy and delivery may have no serious difficulties during the pregnancy and during delivery but over the succeeding years the cardiac disease is most likely to worsen Then the mother would suffer from the stresses of rearing a baby and may become incapacitated or die when the child needs a mother most The much needed mother would leave a young offspring to suffer from the many difficulties of the world and possibly become a teenage problem or a social and economic delinquent Planning and considerations for pregnancy must not only take into consideration the immediate period of pregnancy but the years in the future as well These and other obvious considerations must be foremost in the physician s mind at all times The social economic and family prognoses are the responsibilities of the family physician—the counselor of the patient her husband and her family—as well as of all physicians concerned

If a patient already has young children (three others for example) it must be judiciously determined whether or not she should undertake the risk of another pregnancy possibly to be crippled for life or to die and leave behind a new baby and three young siblings and a father Imagine what could happen to these five people left behind without the mother! Remember the whole family all people must be considered

The physician should discuss with the family certainly with the married couple alone or with whomever else they wish the many implications risks advantages and potential problems that may ensue if pregnancy were to develop in the presence of the cardiac disease state To merely recommend pregnancy and to assist the woman through pregnancy only for the mother to succumb a few years later is not a praiseworthy accomplishment

Once pregnant the patient regardless of her state of health certainly should consult her family doctor immediately to evaluate her state of health and cardiac state in order to determine whether or not pregnancy should be allowed to continue Also remember that some of the drugs required for the care of her heart disease may produce a congenital anomaly in the fetus A cardiologist may be consulted if necessary when a patient is pregnant and has heart disease These health evaluations should be made within the first 3 months of pregnancy and preferably within the first 6 weeks in the event abortion is to be seriously considered When an abortion is considered and is carefully and thoroughly discussed by the family physician and obstetrician first and only after the medical aspects of the problems are thoroughly understood as mentioned for pregnancy evaluation then the patient and her husband should be consulted The cardiac disease state should be properly evaluated and the decisions made as to whether or not pregnancy can or is to continue in spite of the cardiac disease A competent cardiologist may need to be engaged to assist in the evaluation of the risks and in the management of the cardiac disease and to learn the problems to be expected during pregnancy and delivery and even after delivery When advanced heart disease is present the patient should be admitted to the hospital for the last 3 to 4 weeks of pregnancy when necessary to manage the heart disease and the pregnancy The obstetrician decides if when and how to induce labor when induction is necessary

When pregnant patients present themselves

To the readers of the American Heart Journal

Since 1959 I have had the pleasure of serving as Editor of the AMERICAN HEART JOURNAL During this time the Journal has flourished and enjoyed a wide readership which is a credit to the many contributors and to the Editorial Board the many reviewers and The C V Mosby Company all of whom provided excellent assistance to me and to the AMERICAN HEART JOURNAL. I wish to express my thanks to all who have helped make the Journal a success This assistance has come in a large part from readers from all over the world The main objective of the Journal has been to help its readers especially those dedicated to the practice of bedside and office medicine and cardiology I hope the AMERICAN HEART JOURNAL has served this purpose effectively

As I turn the Journal over to a new Editor I wish him and the AMERICAN HEART JOURNAL continued success

Certain principles in the management of heart disease and pregnancy

G E Burch M D
New Orleans La

In addition to health problems due to pregnancy itself a pregnant woman can develop any disease that a non pregnant woman can develop However pregnancy normally imposes changes in the cardiovascular system which usually aggravate any associated illness of the cardiovascular system and which produce extra difficulty with the outcome of the pregnancy The normal and abnormal changes associated with pregnancy are particularly prominent in the presence of heart disease Heart disease is a serious illness in itself without the imposition of pregnancy to increase this seriousness Furthermore there are some cardiac states associated with pregnancy which actually are of little importance but which often concern the patient and her family and her obstetrician Examples include premature heart beats When such rhythm disturbances are present during pregnancy the concern about them becomes even greater than usual Therefore there are certain general clinical medical principles which should be considered in pregnancy Some of these principles are discussed below

Any woman contemplating or planning a pregnancy should be examined carefully for a com

Thermal illness in fun running

John R Sutton MB BS FRCP(C)
Oded Bar Or, M D
Hamilton Ontario Canada

Almost weekly in the medical press, we read of a new complication associated with jogging—bruises blisters sprains tears penile frostbite, excoriated nipples, osteoarthritis myocardial infarction heat stroke asthma hypoglycemia amenorrhea nephropathy etc One could be forgiven for thinking that a pair of running shoes is an invitation to self destruction[1]

These problems multiply when the jogger is encouraged to join his compatriots for a fun run for the addition of the competitive aspect may be an ingredient responsible for the most serious of the fun runner s problems thermal injury Heat stroke is the most serious of the thermal injuries for not only can it kill but the potential number of those severely afflicted is alarmingly large It appears that fun running is still in its ascendancy and now with more than 30 million joggers on the North American continent the number of heat casualties resulting from fun runs could reach epidemic proportions

There are many reports of serious heat injuries heat exhaustion and heat stroke during fun runs in Australia Canada[5,6] New Zealand[7,8] and the United States[9] In the United States experience probably the Peachtree Road Race in Atlanta has produced the greatest number of heat casualties One usually associates heat injury with hot humid environments however, this is not necessarily so in fun runs as the Sydney 'City to Surf' experience demonstrates Heat stroke in runners with rectal temperatures as high as 43° C have been recorded when the ambient temperature was as low as 10° C or a correc effective temperature (which takes i to a count humidity and wind) of only 5° C

What is the predictable setting in which he injury will occur? Obviously the combination environmental factors and the predisposed in vidual will be the right mix for serious he injuries to occur From the City to Surf" expe ence, in the four years from 1976 to 1979 inclusi no case of heat exhaustion or heat stroke h occurred in a registered athlete who has de oped the art of listening to signals of fatigue a stress from the body [11] It is also clear that t risk of sustained heat related injuries is not t same for all runners There are large individ differences in heat tolerance and therefore p disposition to heat injury Following are some the factors known to characterize an indiv d who is at greater risk

1 **Insufficient acclimatization** For an unac matized subject running in a hot environm will produce an excessively high physiolog strain—higher core and skin temperatures a higher heart rate and running capacity w decline markedly This can occur classically wh an athlete is transferred from a cool to a h environment if training is done in the cooler pa of the day but competition is conducted in of the day or if there is an unexpec heat of the day or if there is an unexpec climatic change It takes about 5 to 10 run sessions in the new climate before these str indices return to previous levels and only t will the runner perform at his previous level the transition period athletes should reduce b the intensity and duration of training runs It been clearly shown that a disregard for th precautions will lead to unduly high heat stor and predisposition to heat illness including h stroke [13,14]

in pregnancy with heart disease the physi and obstetrician and the anesthesiologist consult in regard to managing the future of the pregnancy Such problems must be dividualized since no two situations are precise ly the same Close cooperation of all physicians is essary to render adequate service to the preg patient

The methods of managing a patient who is and suffering from heart disease will upon many factors It is impossible to ndicate the management in detail or even to list all of these factors The best cardiologist and the best obstetrician are necessary for the most severe uations The technics of delivery etc must be left to the obstetrician and the anesthesia to the anesthesiologist after the clinical situation has been thoroughly studied and discussed by these physicians The general physician and/or cardiol ogist must begin their management of the heart disease as early as possible prior to delivery It is a mistake to wait to start cardiac therapy or to begin anticipating problems until after they have occurred Proper early predelivery management with proper planning prior to delivery for the time of delivery with anticipation of problems can e for a successful and happy outcome Management continues during the puerperal peri od Decisions do not end with a successful deliv ery Continued management of the cardiac dis ease and considerations of the prevention of future pregnancies is mandatory

With greater emphasis on prepregnancy exami nations and with routine premarital and prepreg nancy examinations with thorough discussions the problems related to heart disease and preg nancy could be reduced to a minimum and deaths of mothers due to heart disease and pregnancy could be practically eliminated The time to learn about the safety or hazards of pregnancy is *prior* to pregnancy This is true not only for heart disease but for all other disease states as well Young girls and women who have not had a thorough medical evaluation including a cardiac examination should have one prior to engaging in sexual activity with possible resultant pregnancy Such an evaluation certainly is indicated immedi ately after detecting pregnancy The decision to follow up these studies must be individualized

When patients with heart disease are not seen until the last trimester of pregnancy or just prior to the onset of labor the family physician and/or cardiologist must work closely with the obstetri cian and anesthesiologist in management with all necessary preparations procedures and equip ment being made available during delivery The patient with heart disease regardless of how mild the problem should be continually managed by the family or primary doctor Congestive heart failure offers the greatest difficulty This is espe cially true when acute congestive heart failure develops during delivery Shock or serious cardiac arrhythmia may further worsen the clinical prob lems All of these complicated cases are most difficult to manage even by experts with consid erable experience

loads than when exercising in neutral environments[45] Surprising to some may be the fact that death from hypothermia may occur in fun runs when the exhausted lightly clad athlete runs in a cold windy environment[6]

It would therefore seem that jogging may not be safe at any time of the year But there is another side isn t there? Far from trying to stifle the present worship of physical activity, which shows no signs of being just a passing fad we too are of the faith and have also suffered some of the wounds albeit minor, of the jogging martyrdom However we do want to add a note of caution when we encourage people to be active and participate because if they are injudicious they may pay a heavy price Above all we must keep the fun in fun runs!

2 Lack of conditioning Conditioning in a cool climate can only partially substitute for exercise in the heat as a means for acclimatization Still the less conditioned female[15, 16] or male[1, 1] runner does seem to be less heat tolerant Less conditioned individuals also take longer to acclimatize to heat [19] Inexperienced runners may sustain heat stroke during races not necessarily due to low fitness level but rather because they select a running speed which is too fast for their ability [9]

3 Dehydration Progressive dehydration commonly occurs during long distance running even when fluids are supplied ad libitum Although the runner can perform well while being dehydrated, extreme fluid losses predispose one to heat stroke and acute renal failure Of special importance is the hydration level prior to a run Those who start exercising while dehydrated reach a higher core temperature than they would when fully hydrated prior to the exercise [3] Thus if a runner neglects to be fully hydrated before a prolonged run the risk of inadequate heat dissipation is magnified When progressively dehydrating during prolonged exercise children and obese individuals [5] have a greater rise in core temperature than do lean young adults

4 Age extremes Both young children and elderly people are more susceptible than young adults to climatic heat waves [6] During prolonged exercise in the heat children were found to have shorter tolerance time than had young adults [13, 27, 30] *This difference is especially evident* in very hot climates (dry bulb exceeding 40 C) and is attributable to greater surface area/mass ratio lower sweating rate greater metabolic heat production and a less efficient convection of heat from core to skin in the child Young adolescents and children[31] can acclimatize to heat However children need more time than adults to reach sufficient acclimatization [3] Possible causes for low heat tolerance among the exercising elderly are a lesser sweat production and a lower aerobic capacity [27]

5 Obesity Obese teenagers and adults are less heat tolerant than are lean individuals The clinical relevance is that exercising overweight and obese people are at greater risk for heat illness including nephropathy and fatal heat stroke [34, 37]

6 Prior heat stroke What is the risk for a runner with a history of heat stroke to have a relapse during subsequent running? Young adults who had sustained heat stroke during a prolonged march in hot weather were given 2 to 5 years later an exercise test in a heated climatic chamber None of them managed to complete the task which was successfully completed by healthy controls [6] The reasons for incompletion were exhaustion or excessively high core temperature and heart rate Deficient thermoregulatory capacity in people who had a history of heat stroke was also described by Robinson and coworkers

An important question is whether such people have inherent deficiencies or whether their thermoregulatory capacity became irreversibly affected *during* the heat stroke episode This question cannot be answered by the above retrospective studies At any rate runners with a previous history of heat stroke are at a higher risk of recurrence and should be advised to avoid intense running in hot weather

Management

Much ha been written about the management of heat injuries and obviously prevention is the key particularly when one considers the large number of predisposed individuals in fun runs These findings have been adequately reviewed elsewhere [1, 4, 4] In general the recommendations have fallen into three categories (1) those related to *race organization*—i e timing of the race during the day and time of year possible cancellation of the race if heat stress indices reach extreme levels provision of adequate fluids (2) *competitor education*—information regarding training heat acclimatization awareness of potential problems and likely premonitory symptoms and (3) *medical management and organization* and provision of first aid stations and on site emergency treatment facilities for the rapid cooling of patients *

We have concentrated on heat injury in our coverage of the thermal problems related to fun runs as these cases are obviously numerically the most important However problems from cold or dry air arise in fun runners particularly those who may develop exercise induced asthma [3, 4] and those with ischemic heart disease who will develop angina on a cold day at lower exercise

N B S ce the inst t ti n of these rapid cooling f cil t es during the City to-Surf™ race there ha e been no serious sequel e f h t stroke in almost 100 000 competit rs

Although the higher incidence of mortality and morbidity for cardiovascular events in patients with diabetes mellitus (DM) compared with nondiabetic patients has evidentiated the role of DM as an independent risk factor for cardiovascular disease controversies still exist about the severity of coronary artery disease (CAD) in diabetic (D) compared to nondiabetic (ND) patients While some studies have shown an equal incidence of CAD others have reported a higher grade of severity of CAD in D patients compared to ND patients

Such controversies led us to re examine our data on 34 diabetic patients who had undergone selective coronary arteriography in the last 2 years in our institution and who were found to have significant CAD and to compare their clinical hemodynamic and angiographic findings with those of a control group of 120 nondiabetic patients with CAD studied consecutively in the same period of time

Patient population

Results

Table I shows the principal hemodynamic data for both groups These results also include 7 diabetic patients in whom only hemodynamic data were obtained *without* angiographic studies Diabetics presented a lower cardiac index and left ventricular dP dT max but these differences were not statistically significant

The extent of CAD in diabetic and nondiabetic patients is shown in Fig 3 SVD was found in three of 34 diabetic (9%) and in 36 of 120 nondiabetic patients (30%) ($p = 0.025$) multivessel disease (DVD/TVD) was present in 31 of 34 diabetic (91%) and in 84 of 120 nondiabetic patients (70%) ($p < 0.025$) Number of coronary stenoses per patient was 2 47 in diabetic and 2 09 in nondiabetic patients ($p < 0.025$) (Table II)

Fig 4 shows the distribution of CAD on major coronary arteries Left anterior descending (LAD) was significantly involved in all 34 diabetic patients (100%) and was predominantly involved in nondiabetic patients (10? of 120 8?%) This difference between diabetics and nondiabetics had statistically significant results ($p < 0.005$) Right coronary artery (RCA) stenosis was found in 27 of 34 diabetic (79%) and in 8? of 120 nondiabetic patients (69%) Circumflex coronary artery (Cx) involvement was present in 21 of 34 diabetic (62%) and in 66 of 120 nondiabetic patients (55%) Incidence of complete coronary artery occlusions is also shown in Fig 4 At least one coronary occlusion was found in 15 of 34 diabetic (44%) and in 48 of 120 nondiabetic patients (40%) A total of 20 occlusions was found in the 15 diabetic patients (1 33 occlusions per patient) a total of 55 occlusions was found in the 48 nondiabetic patients (1 15 occlusions per patient) In both groups LAD and RCA were more frequently and almost equally occluded LAD occlusion was present in eight of 34 diabetic (23%) and in 25 of 120 nondiabetic patients (20%) Cx was occluded in four of 34 diabetic (12%) and in six of 120 nondiabetic patients (5%) Such differences were not statistically significant

Fig 5 shows the results of left ventriculography Eight of 32 diabetic (25%) and 56 of 115 nondiabetic patients (49%) presented with normal left ventriculography or only a localized asynergy ($p < 0.025$) No differences between diabetic and nondiabetic patients were found in the incidence of diffuse asynergy (14 of 32 diabetic 44% vs 43 of 115 nondiabetic patients 37%) Left ventricular *aneurysm* was present in 10 of 32 diabetic (31%) and in 16 of 115 nondiabetic patients (14% $p < 0.025$) In order to evaluate if the latter difference had to be attributed to *different severity or distribution of CAD* or to different development of collateral circulation we analyzed these factors in the 10 diabetic and in the 16 nondiabetic patients with LV aneurysm (Table III) No significant differences resulted in severity of CAD incidence of occlusion of the coronary artery supplying the aneurysmatic seg

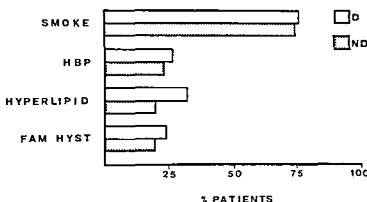

Fig 1 Incidence of risk factors for coronary artery disease in 34 diabetic *(D)* and 120 nondiabetic *(ND)* patients.

ere found in two diabetic patients (6%) and in 27 ondiabetic subjects (22%) Ischemic changes on e electrocardiogram were present in 14 diabetic atients (41%) and in 65 nondiabetic subjects 4%) A history of myocardial infarction (MI) as present in 20 diabetics (59%) and in 68 ondiabetics (57%) Cardiomegaly on chest x ray as found in 18 diabetic patients (52%) and in 50 ondiabetic subjects (42%) Mean duration of mptoms was 49 2 months in diabetics and 40 8 onths in nondiabetics None of the above differ nces was statistically significant

In both groups the indication for cardiac cath terization and coronary arteriography was given ased on the presence of angina stable or unsta le nonresponding to intensive medical manage ent or on the presence of symptoms such as entricular arrhythmias or atypical chest pain hen it was important to exclude or confirm the inical suspicion of CAD or finally on the resence of otherwise unexplained symptoms of ft ventricular (LV) failure

Methods of study All patients underwent car iac catheterization left ventriculography and elective coronary arteriography with the Sones echnique[1] Pressures were recorded with Sta ham P23Db transducers on an OTE photograph c recorder Cardiac output was measured by the hermodilution technique[3] Left ventriculogra hy was obtained by injecting 45 c c of Urografin 76% in the left ventricle at 15 c c /sec speed with Viamonte Hobbs injector with the patient posi ioned in the right oblique and sometimes also in the left oblique projection Selective coronary arteriography was also performed in multiple projections Left ventriculography and coronary arteriography were recorded on Kodak film with

ment and extent of collateralization to the infarcted myocardial area

Discussion

Patients with and without diabetes mellitus showed similar incidence of CAD risk factors such as systemic hypertension smoking habits and family history of CAD Differences in age and incidence of hyperlipidemia were only minimal and were not statistically significant Although the presence of diabetes mellitus might influence the indication to cardiac catheterization and thus preselect patients with more severe CAD this was unlikely to be the case in our population Over the last two years we felt that the poor angiographic quality of coronary arteries in diabetic patients which rendered them not suitable for aortocoronary bypass grafts did not justify reserving coronary arteriography only in diabetic patients with more severe angina In fact although in our study diabetics showed a slightly larger incidence of angina compared to nondiabetic patients (94% vs 78%) the frequency of the more severe type of angina (unstable) was practically the same (56% vs 51%) and all other clinical parameters that we analyzed were comparable Thus we feel that diabetic and nondiabetic patients in our study can be considered as two matched groups with CAD only differing in the presence or absence of diabetes mellitus which by itself should explain the differences in the severity and distribution of CAD between the two groups

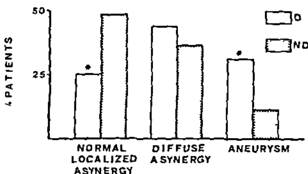

Fig 5 Findings at left ventriculography in 3? diabetic *(D)* and 115 nondiabetic *(ND)* patients $p < 0.025$ D vs ND

Other authors have compared the extent of CAD in diabetic and nondiabetic patients based upon angiographic[6, 8] or pathologic[4, 5, 9, 11, 16] data Recently Dortimer and associates[8] reporting coronary arteriographic findings in 37 diabetic and in 79 nondiabetic patients matched for age sex and CAD risk factors, have described in patients with diabetes mellitus a significantly higher number of diseased coronaries per patient and a higher although not significant incidence of TVD compared to nondiabetic patients Furthermore they found no differences in the distal distribution of CAD in the incidence of bypassable vessels distal to a significant stenosis and in the frequency of collaterals to occluded coronaries They did not comment though on differences in the degree of impairment of LV segmental contraction between the two groups In

Combined mexiletine and amiodarone treatment of refractory recurrent ventricular tachycardia

A Waleffe MD PhD
L Mary Rabine MD FACC
V Legrand MD
J Cl Demoulin MD
H E Kulbertus MD FACC
Liège Belgium

Refractory recurrent ventricular tachycardia represents a difficult therapeutic problem In most cases the rhythm disorder ultimately requires the administration of a multiple drug regimen Potentiation of the efficacy of one drug by the other is possible and satisfactory clinical results may be expected with lower doses than if each agent were given singly This might decrease the incidence of at least some of the side effects

The present paper is concerned with the results obtained in nine patients by using the association of a class I antiarrhythmic agent (mexiletine) with a class III agent (amiodarone)

Description of patients and methods

The study group consists of nine male patients ranging in age from 23 to 64 years (mean 53 4 years) and suffering from recurrent episodes of documented ventricular tachycardia The first three of these cases were very critically ill individuals who had spent 10 days or more in the intensive care unit with at least five episodes of ventricular tachycardia daily (Table I) In each instance several antiarrhythmic agents had been administered in classical dosage without any success It is to be noted that all three patients had received intravenous mexiletine at a dose of 1 500 mg per day This had reduced or suppressed the episodes of arrhythmia but serious gastrointestinal disorders (vomiting) had developed in all three and neurological side effects consisting of convulsions (type grand mal) had occurred in one (patient No 3) Reduction of the dose to 1000 mg per day had allowed the rhythm disorder to recur The remaining six cases (Table II) had a diagnosis of coronary artery disease (five patients) or congestive cardiomyopathy (one patient) They all had suffered repeated episodes of ventricular tachycardia which could not be prevented by the various drugs previously administered These patients were referred to the laboratory of clinical electrophysiology for determination of optimal pharmacological therapy After informed consent all cardioactive drugs were discontinued for at least 72 hours before the electrophysiologic investigation by programmed electrical stimulation of the heart was conducted The methods apparatus and definitions used have been previously described[1] The stimulation sequence which permitted the induction of ventricular tachycardia was characterized by using different atrial and ventricular pacing rates (up to ... /minute) and one to four ventricular premature depolarizations Once initiation of tachycardia was achieved by pacing the treatment by amiodarone and mexiletine was begun as indicated below To judge the efficacy of this drug regimen the patients were submitted to iterative electrophysiologic testing on days 5 and 7 after initiation of therapy On each occasion the complete program of atrial and ventricular stimulation was repeated

mexiletine and is totally asymptomatic (follow up 9 months) Patient No 7 received no antiarrhythmic therapy after his operation Five months later he presented a recurrence of his rhythm disorders and a control left ventricular angiogram demonstrated the reappearance of a voluminous inferior aneurysm the patient was reoperated upon and died during surgery Patients No 3 4 8 and 9 are all presently asymptomatic In one of them (patient No 3) the development of gastrointestinal discomfort at 5 weeks led to the replacement of mexiletine by another class I agent (aprindine 100 mg/day) Patient No 4 still presents on ambulatory monitoring rare bouts of ventricular tachycardia which show a rate of 100 beats/minute and which are not perceptible to the patient

Discussion

The pharmacological treatment of recurrent life threatening ventricular tachycardia constitutes a difficult problem Most investigators agree with Zipes that it may be as naive to think that one antiarrhythmic drug will be effective for all patients as it is to think that one antibiotic will cure all infections

In this respect it seems logical to admit that at least in difficult cases the administration of an association of drugs may become necessary

Intracellular recordings on atrial and ventricular

Table I Clinical features of the first three cases treated by mexiletine + amiodarone

Case no	Age (years)	Sex	Diagnosis	Arrhythmias	Previous treatment IV or oral
1	64	Male	3 attacks of myocardial infarction left and right ventricular failure	VF VT multifocal VPBs	Lidocaine Diphenylhydantoin Practolol Procainamide Mexiletine digoxin Prazosin

3	62	Male	2 attacks of posteroinferior myocardial infarction residual angina (aorto coronary bypass grafts on the anterior descending and circumflex arteries)	VT VPBs	Xylocaine Disopyramide Propranolol Mexiletine

plus DC shock whenever necessary
AF atrial fibrillation VT ventricular tachycardia VF ventricular fibrillation VPB ventricular premature beats.

The treatment was given as follows During the first two days mexiletine and amiodarone were perfused intravenously at a dose of 1 000 mg and 1,500 mg per 24 hours respectively Simultaneously amiodarone was also given orally at a dose of 600 mg per 24 hours From day 3 onwards the intravenous administration was interrupted and both drugs were continued orally at a dose of 600 mg daily

Results

In the first three cases the association of amiodarone and mexiletine resulted in total suppression of the tachycardic episodes within the first three days after initiation of treatment No electrophysiological study was performed in those patients who could be released from the intensive care unit to a normal ward after two weeks of therapy

In the last six cases episodes of ventricular tachycardia could easily be triggered by programmed electrical stimulation The morphology of QRS and cycle length during tachycardia are indicated in Table II In all but one patient (No 4) the cycle length of the electrically induced tachycardia was shorter than the cycle length of the spontaneous epidoses even when the QRS morphology was identical In addition in five out of the six instances it was possible to induce during ventricular programmed stimulation tachycardic epidoses showing different QRS morphologies and cycle lengths This pleiomorphism was associated with the existence of large aneurysmal or akinetic areas as observed at left ventricular angiography or blood pool scans After five days of treatment no tachycardia could be elicited in patients No 6 7 8 and 9 When the six subjects were retested on day 7 none developed ventricular tachycardia

The follow up of these patients is still rather short (Table III) Patients No 1 and 2 remained *free from ventricular tachycardia but died after 2* and 5 months from intractable heart failure One of them (patient No 2) who was known to have a sick sinus syndrome developed under the influence of treatment a severe symptomatic bradycardia which justified implantation of a pacemaker Another patient (No 6) was lost to follow up soon after his release from hospital He was brought dead to the emergency department 4 1/2 months later and we were not able to find out whether he had continued his treatment in the meantime This patient had had a large anterior myocardial infarction He had a cardiomegaly and a large aneurysmal formation Two patients (No 5 and 7) who had suffered no relapse of tachycardia underwent cardiac surgery at 6 weeks (*triple aortocoronary bypass graft*—*patient* No 5) and 8 weeks (aneurysmectomy—patient No 7) respectively Patient No 5 presently remains on

Table III Follow up

1	2	Died from intractable heart failure
2	5	Died from intractable heart failure
3	9	At 5 weeks gastrointestinal discomfort Replacement of mexiletine by aprindine (100 mg daily) Asymptomatic
4	5	Asymptomatic Rare bouts of slow VT depicted at Holter monitoring
5	9	Triple aortocoronary bypass grafts at 8 weeks Asymptomatic
6	4½	Lost to follow up Sudden death
7	8	Aneurysmectomy at 6 weeks No antiarrhythmic therapy after operation Recurrence of VT at 7 months when administration of amiodarone and mexiletine was reinstated Documented recurrence of left ventricular aneurysm Died at surgery
8	4	Asymptomatic
9	6½	Asymptomatic
	58	

whereas no arrhythmia could be triggered in any of them after seven days of administration

The short term results obtained with the association of amiodarone with mexiletine were surely encouraging since spontaneous recurrence of the arrhythmia was prevented in all nine cases After one week of treatment no ventricular tachycardia could be started by electrophysiologic testing in the six cases in whom tachycardic episodes had easily been initiated prior to the initiation of therapy

The long term follow up reflects the over all rather poor prognosis of patients suffering from this type of rhythm disorder Patient No 3 who died suddenly presented with all the markers of the highest risk group among postinfarction patients [6] He had had a large anterior transmural myocardial infarction He had a cardiomegaly an aneurysmal formation and clinical and angiographic evidence of left ventricular dysfunction of a severe degree His demise was not unexpected and we do not even know whether he continued his treatment after his release from the hospital

The other two subjects who died also had a guarded prognosis from the start They had shown signs of severe right and left heart failure in the intensive care unit In spite of the disappearance of their arrhythmia they soon died in intractable cardiac decompensation It is impossible in these cases to rule out a deleterious influence of the antiarrhythmic treatment on cardiac function In two patients the drug association permitted us to perform safely the invasive investigations which preceded a surgical procedure One of these subjects is now doing well the other died after a recurrence of his left ventricular aneurysm and simultaneously of his rhythm disorder He was receiving no antiarrhythmic therapy at the time of his relapse The other patients remain asymptomatic even if one of them still shows bouts of slow ventricular tachycardia on ambulatory monitoring

In this study the efficacy of the drug cover was assessed by repeated electrophysiologic testing Although the technique still deserves further evaluation in long term follow up studies it is thought to provide a good and fast way of selecting the drug regimen which should best protect the patients Several recent reports suggest that the results yielded by this method correlate reasonably well with the effectiveness of long term suppressive therapy [9,14] Although the follow up of our patients is relatively short the present observations are in agreement with this opinion

This report admittedly lacks the strong impact of a controlled study However all practitioners realize the difficulty of controlled studies in patients with life threatening arrhythmias In this situation ethical problems almost always prevent the application of a rigourous scientific methodology Nonetheless it is for this very group of patients that effective antiarrhythmic therapy is most needed We believe that the present data provide sufficient evidence to indicate that the association of a class I with a class III agent may be of interest in the therapy of individuals with refractory recurrent ventricular tachyarrhythmias It is apparent however that

lar muscle cells have indicated that mexiletine has, according to Vaughan Williams classification,[3] a typical class I action causing a significant reduction of maximum rate of depolarization with no change of resting potential. Like lignocaine, mexiletine shortens the action potential in all cardiac tissues but this effect is particularly conspicuous in that portion of the conduction system which has the longest action potential duration. As a result of this differential effect, action potential duration becomes uniformly short. Some investigators have suggested that the greater uniformity of action potential duration may contribute to the antiarrhythmic action of the drug. Vaughan Williams has questioned this opinion.[3] He believes to the contrary that the shortening of action potential might be arrhythmogenic and expresses the feeling that the antiarrhythmic effect of mexiletine can be attributed to its class I action and that this exists in spite of the shortening of action potential. In view of this, one is tempted to wonder whether there might not exist a synergistic action between class I agents and substances which, like amiodarone, prolong the action potential duration (class III of Vaughan Williams classification). This assumption prompted us to use the association of mexiletine and amiodarone in our patients.

It should be pointed out that our work was not designed to try and demonstrate that the association of amiodarone with mexiletine is clinically superior to either drug given alone. The purpose of this paper is simply to report on the results obtained with this double drug regimen in patients with life-threatening refractory ventricular tachyarrhythmias. It is worthy of note, however, that seven of our patients had previously received mexiletine given singly; two others had received amiodarone. The treatment had been judged unsatisfactory either because of unresponsiveness or because of the appearance of untolerable side effects.

The mode of administration was selected according to the pharmacokinetics of each of the drugs which were administered. Mexiletine is known to require a loading dose on the initiation of chronic oral therapy.[6] This justified the parenteral administration during the first 2 days. No plasma level of mexiletine could unfortunately be obtained to demonstrate that a steady state plasma concentration within the therapeutic range was achieved. The pharmacokinetics of amiodarone are less well known and its investigation has always been hampered by the absence of a reliable method for drug plasma level determinations. It is known on a clinical basis that several days of treatment by amiodarone at 600 mg per day are required for the full antiarrhythmic efficacy to become manifest.[7] This delay is thought to reflect the time which is necessary to build up sufficient concentrations of the drug within the myocardial cells. Amiodarone was therefore used intravenously during the first two days of treatment with the hope that this would shorten this delay and improve the reliability of drug cover. It is likely, however, that the particular characteristics of amiodarone's clinical pharmacology explains why two patients were not yet totally protected after five days of treatment

In this study the efficacy of the drug cover was assessed by repeated electrophysiologic testing Although the technique still deserves further evaluation in long term follow up studies it is thought to provide a good and fast way of selecting the drug regimen which should best protect the patients Several recent reports suggest that the results yielded by this method correlate reasonably well with the effectiveness of long term suppressive therapy Although the follow up of our patients is relatively short, the present observations are in agreement with this opinion

This report admittedly lacks the strong impact of a controlled study However all practitioners realize the difficulty of controlled studies in patients with life threatening arrhythmias In this situation ethical problems almost always prevent the application of a rigourous scientific methodology Nonetheless it is for this very group of patients that effective antiarrhythmic therapy is most needed We believe that the present data provide sufficient evidence to indicate that the association of a class I with a class III agent may be of interest in the therapy of individuals with refractory recurrent ventricular tachyarrhythmias It is apparent however that

this treatment will not be able to protect patients at highest risk especially those in whom the proportion of functionally viable myocardium is too small It may however be most helpful in less severe cases or during the period which precedes a surgical procedure consisting of coronary bypass grafting or aneurysmectomy

Summary

A combined mexiletine and amiodarone treatment was applied in nine cases with recurrent *refractory ventricular tachycardia* During the first two days of treatment mexiletine and amiodarone were perfused intravenously at a dose of 1 000 mg and 1 500 mg per 24 hours respectively Simultaneously amiodarone was also given orally at a dose of 600 mg per 24 hours From the third day onwards the intravenous administration was interrupted and both drugs were continued orally at a dose of 600 mg daily

The first three patients were very critically ill and had had at least five episodes of ventricular tachycardia per 24 hours during the last 10 days in the intensive care unit The treatment resulted in total suppression of the tachycardic episodes within three days after initiation of therapy

In the remaining six cases ventricular tachycardia was easily initiated by programmed electrical stimulation of the heart No arrhythmia could be elicited by repeated testing on the seventh day of treatment

The mean follow up period was 6 months Two patients with poor left ventricular function died in intractable heart failure Another one died suddenly 4 ½ months after his release from the hospital He had a large aneurysm and whether he continued his treatment is unknown A fourth patient had an aneurysmectomy he suffered a recurrence and died at his second operation All the others presently remain asymptomatic

The association of a class I (mexiletine) with a class III (amiodarone) agent is theoretically attractive for the treatment of refractory ventricular arrhythmias

The present findings corroborate this hypothesis but show that this association is not able to protect individuals with severe underlying myocardial damage

The authors would like to express their gratitude to Mrs B Vervier and F Courtois for their helpful secretarial and technical assistance

therapy accompanied by an elevated (> 120 mg dl) fasting blood sugar Radiologic evaluation and interpretation for cardiomegaly was performed by a radiologist

Electrocardiographic QRS voltage limits suggesting *left ventricular hypertrophy* were based on accepted criteria[1] Twelve lead standard electrocardiograms taken on all patients were reviewed by at least two of the authors and a diagnosis of left ventricular hypertrophy was made on the basis of a combination of several but not necessarily all of the following electrocardiographic findings S wave in Lead V_1 plus R wave in Leads V_5 or V_6 > 35 mm R wave in Lead aV > 11 mm R wave in Lead I plus S wave in Lead III > 25 mm or R wave in Lead aV_F > 20 mm ST T segment and T wave deflection (with or without digitalis) in a direction opposite to the main QRS was noted Left atrial enlargement (LAE) was diagnosed if the terminal negativity of the P wave in Lead V was 1 mm or more in depth accompanied by a duration of 40 msec or more The Romhilt Estes point score system for ECG diagnosis of left ventricular hypertrophy was also utilized[1] The ECGs in the 57 control patients (normal QRS ECG group) were in all instances reviewed by two readers who agreed that the QRS was normal

The various *methods utilized* to evaluate patients in this study have been previously described in detail[1] Essentially all patients underwent right and left heart catheterization as well as left *ventricular and selective coronary* angiography Left ventricular angiograms were performed to evaluate wall motion and to determine end diastolic volumes and ejection fractions The left ventricular contractile pattern was determined by superimposing the end-diastolic and end systolic silhouette of the left ventricular angiogram utilizing criteria previously described Selective coronary arteriograms were reviewed to determine the number of major arteries (left anterior descending circumflex and right coronary artery) involved with significant *disease—i e narrowing of an artery* by more than 50% of the wall lumen The severity of involvement of each of the major coronary arteries was graded on the basis of a score from 0 to 6 as defined by Bruschke[4] *The total coronary score* was the sum of the scores of the three major coronary arteries Involvement of the main left coronary artery was considered separately All information was *tabulated and evaluated by* standard statistical methods

Results

LVH ECG group vs normal QRS ECG group The clinical profile of patients meeting electrocardiographic criteris for left ventricular hypertrophy (LVH ECG group) is shown in Table I and is compared with 57 patients matched for both age and sex but having a normal QRS complex (normal QRS ECG group) The duration of symptoms in these two groups of patients were not significantly different and in all instances the patients were evaluated because of angina pectoris However 25% of the patients in the LVH ECG group had a history of congestive heart failure compared to none in the normal QRS ECG group ($p < 0.005$) Hypertension was noted

LVH) without evidence of a prior transmural myocardial infarction or intraventricular conduction disturbance These patients represent only 3 9% of our population of patients with ischemic heart disease seen during a four year period Conclusions based on this study are thus limited by the patient referral and the criteria for selection into the study

This study was motivated by the prospective epidemiological work of Kannel and associates [11] and Chiang and co workers In the Framingham study a threefold increased risk of developing coronary artery disease was noted in the presence of ECG LVH even after adjustment for the effect of coexisting hypertension ECG LVH was associated with an increased risk of all clinical manifestation of coronary artery disease and in particular with a coronary death In 40% with ECG LVH death occurred as the initial coronary event Combining the experience from both Framingham and Albany[9] indicated that ECG LVH and the presence of another coronary risk factor strongly suggested the presence of occult coronary artery disease Men with ECG LVH had a fivefold increase in risk of sudden death[9] and 29% presented with sudden death compared to 10% among those without this electrocardiographic abnormality Thus the Framingham study suggested that ECG LVH was a marker of latent coronary artery disease and was associated with an ominous prognosis In the Tecumseh Study [10] the six year incidence of sudden death (per 1 000 population) in those with ECG LVH was 48, compared to 2[illegible] in those with a normal electrocardiogram and almost comparable to subjects demonstrating ventricular premature be[illegible] (61 of 1 000 population) In a study by Dison a[illegible] associates [19] ECG LVH in patients having co[illegible] nary artery disease was associated with a sig[illegible] cant ($p < 0.005$) linear correlation for a cardi[illegible] death

The present study demonstrates both clini[illegible] and hemodynamic findings of significa[illegible] impaired left ventricular function in a large nu[illegible] ber of patients with ECG LVH This was read[illegible] evident in comparison to age sex matched co[illegible] trols also referred because of symptomatic co[illegible] nary artery disease but without ECG LVH [illegible] both groups of patients (ECG LVH and ECG normal QRS) there was no significant differe[illegible] in the duration of symptoms and no patient ha[illegible] clinical history of electrocardiographic evide[illegible] of a prior myocardial infarction The difference in left ventricular function (Fig 1) between the two groups of patients could not be explained [illegible] the basis of the severity of the coronary arte[illegible] disease (Table I) Hypertension as expected w[illegible] present in three quarters of the patients [illegible] ECG LVH and no doubt contributed to the [illegible] ings in the present study The combination [illegible] hypertension and ECG LVH was present in [illegible] patients In our experience[15] 30% of pati[illegible] patients In our experience[15] 30% of patients evaluated with coronary artery disease have [illegible] documented hypertension Thus of the [illegible] patient population reviewed (1 46? patients) [illegible] had hypertension but only 10% had ECG LV[illegible] Hypertension in combination with corona[illegible] artery disease could well explain the high [illegible] dence of left ventricular dysfunction observed [illegible] the present study in our ECG LVH group H[illegible]

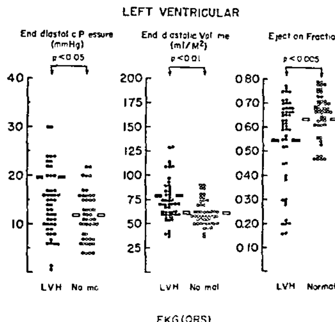

Fig 1 Parameter of left ventricular function evaluated in study patients *Each point* represents the value of an individual patient with *the horizontal bar* being the mean for each group

tions Of the remaining 54 patients in normal sinus rhythm 24 had normal P wave contours while 30 had left atrial enlargement by ECG Evaluating these two subgroups (left atrial enlargement present or absent) with left ventricular hypertrophy revealed no significant differences in their clinical profile except for a greater frequency ($p < 0.05$) of cardiomegaly in the subgroup with left atrial enlargement (59% vs 29%) The left ventricular hemodynamics and angiographic findings in these two subgroups with left ventricular hypertrophy are shown in Table III Of note is the significantly ($p < 0.01$) lower ejection fraction in the subgroup with left atrial enlargement An abnormal ejection fraction (< 0 5) was present in 43% with left atrial enlargement by ECG compared to 13% with normal P waves ($p < 0.025$) Furthermore 73% of patients with such atrial enlargement had an abnormal left ventricular contractile pattern compared to 38% without atrial enlargement ($p < 0.01$) Single vessel coronary disease was more frequent (29% vs 3%) in the subgroup without atrial enlargement ($p < 0.01$) The frequency of main left coronary artery disease was 7% and 17% respectively in those with and without left atrial enlargement

ECG LVH group—ST T wave changes vs normal ST T wave Finally an evaluation of the LVH ECG group on the basis of ST segment and T wave changes revealed that of the 44 patients with such changes 57% had cardiomegaly compared to 23% in those without ST and T wave abnormalities ($p < 0.05$) Congestive heart failure was also more frequent (30% vs 8%) in those with ST segment and T wave changes Left ventricular hemodynamics revealed no significant differences when evaluated on the basis of the presence or absence of ST segment and T wave Generalized hypokinesia was present in six patients with ST and T wave abnormalities In all of these the left ventricular end diastolic pressures volumes and ejection fractions were abnormal The severity of the coronary artery disease revealed no significant differences when those with ST segment and T wave abnormalities were compared to those with normal ST and T waves

No relationship was observed between the Romhilt Estes point score of left ventricular hypertrophy and any parameter of left ventricular function—i e end-diastolic pressure volume ejection fraction or contractile pattern Similarly the severity of coronary artery disease could not be related to the LVH point score

Discussion

The present report reviewed a select subset of patients referred because of angina pectoris not readily controlled by medical management The criteria for selection was documented coronary artery disease and an electrocardiogram demonstrating left ventricular hypertrophy (ECG

left ventricular dysfunction (Table III) Prior studies by Rios and co workers[1 36] demonstrated that left atrial enlargement in patients with coronary artery disease is correlated with left ventricular dysfunction Thus, left atrial enlargement in patients with coronary artery disease was associated with a higher left ventricular end diastolic pressure and increased frequency of left ventricular contractile abnormalities Further it was observed[15 36] that left atrial enlargement was also associated with increased severity of coronary artery disease, a finding not confirmed in our patient population with ECG LVH All three patients with ECG LVH combined with atrial fibrillation had severe left ventricular dysfunction Evaluating ECG LVH further on the basis of abnormal ST segments and T waves was not found helpful in identifying a subgroup with either left ventricular dysfunction or more severe coronary artery disease

From the observations it is concluded that ECG LVH in patients with ischemic heart disease defines a group of patients with an increased frequency of left ventricular dysfunction especially if ECG left atrial enlargement is also present This finding cannot be explained on the basis of prior myocardial infarction No patients had a clinical history or electrocardiographic evidence of such infarction The presence of myocardial hypertrophy and coronary artery disease would certainly bring on a disparity between oxygen demand and supply which, if protracted, could result in ischemic myocardial fibrosis The stimulus for myocardial hypertrophy be it hypertension or chronic ischemia results in increased muscle mass receiving a limited oxygen supply The subgroup of patients with ECG LVH and no prior history of hypertension presented with an excess frequency of main left coronary artery disease On the basis of these findings as well as prior clinical observation it certainly appears warranted that patients with ECG LVH and suspected coronary artery disease should undergo full evaluation in order to define the coronary anatomy and left ventricular function

Summary

The present investigation defines left ventricular function and coronary artery anatomy in a group of patients with electrocardiographic evidence of left ventricular hypertrophy (ECG LVH) and documented coronary artery disease The ECG LVH group consisted of 57 pa[illegible] who were matched with age/sex controls [illegible] patients were evaluated because of angina pec[illegible]ris and no patient had a history or ECG eviden[illegible] of prior myocardial infarction The duration [illegible] symptoms in both groups was not significa[illegible] different Hypertension (75% vs 30%) conges[illegible] heart failure (25% vs 0%) and cardiomegaly ([illegible] vs 4%) were significantly more frequent in t[illegible] ECG LVH group The ECG LVH group demo[illegible]strated greater left ventricular dysfunction [illegible] evident in a higher left ventricular end-diasto[illegible] pressures (20 ± 8 vs 12 ± 9 mm Hg) e[illegible] diastolic volumes (80 ± 28 vs 66 ± 2? ml/m[illegible] and lower ejection fractions (0 55 ± 0 20 [illegible] 0 64 ± 0 17) The severity of the coronary art[illegible] disease as reflected by the number of ves[illegible] involved and total coronary score revealed [illegible] significant group differences The ECG L[illegible] group was further divided based on ECG [illegible] atrial enlargement (LAE) Such evidence of L[illegible] was associated with a higher frequency (p < 0[illegible] of cardiomegaly (59% vs 29%) and a significan[illegible] (p < 0 01) lower ejection fraction (0.50 ± [illegible] 0 64 ± 0 17), as well as higher freq[illegible] (p < 0 005) of an abnormal contractile patt[illegible] (76% vs 37%) Evaluation of the ECG LVH gr[illegible] with the Romhilt Estes point score for the L[illegible] or the presence of abnormal ST segments an[illegible] waves revealed no significant difference in [illegible] ventricular function Patients with hyperten[illegible] compared to those with no hypertension reve[illegible] no differences in LVH point score or left vent[illegible]ular function however, main left coronary ar[illegible] disease was significantly (p < 0 05) more frequ[illegible] in the ECG LVH subgroup with no hyperten[illegible] (29% vs 7%)

It is concluded that ECG LVH in patients [illegible] coronary artery disease defines a group [illegible] patients with increased frequency of left ve[illegible] ular dysfunction especially when associated [illegible] LAE Furthermore such ECG findings in [illegible] presence of ischemic heart disease defines a [illegible] group of patients with an excessive frequenc[illegible] main left coronary artery disease These obse[illegible] tions may in part explain the poor progr[illegible] previously described from epidemiological stu[illegible] of patients with ECG LVH and coronary ar[illegible] disease

The authors wish to thank Brenda Hamby and Da[illegible] Horowitz for their assistance given in the preparation of [illegible] manuscript

ever in a review of our data it was observed that hypertensive patients in our control (normal QRS) group were not characterized by left ventricular dysfunction Thus the finding of LVH on the electrocardiogram in a patient with ischemic heart disease suggests that such a finding may be a marker for left ventricular dysfunction

Romhilt and Estes[14] observed on the basis of a point score system that 62 2% of autopsied hypertrophied hearts met enough electrocardiographic criteria for left ventricular hypertrophy to achieve five points Such criteria were more sensitive from patients with both hypertension and coronary artery disease such a combination was associated with an 88 2% sensitivity compared to 45% with only hypertension and 54 4% with only coronary artery disease A comparison of the point score in our patients with ECG LVH in those with an without hypertension revealed no significant differences Utilizing a point score of 5 or more there were only 3 3% false positive

Why 25% of our patients without hypertension had ECG LVH is uncertain It is possible that some of these patients had clinically unrecognized myocardial infarction and prior undiagnosed hypertension It is well appreciated that in some patients preexisting hypertension may not persist after a myocardial infarction [19, 21] It is also possible that the ECG LVH observed in some of our patients represents a conduction disturbance rather than true myocardial hypertrophy Such a hypothesis is based on the investigations of Piccolo and associates [22] who observed that ECG LVH in some patients was dependent on slowed conduction in the left bundle branch system suggesting that the anatomical hypertrophy may play a less important role Such a mechanism for ECG LVH may well explain the low sensitivity of the electrocardiogram in diagnosing anatomic left ventricular hypertrophy [1, 14] Finally it is well recognized that coronary atherosclerosis per se may be associated with cardiac hypertrophy Pathologic studies [3, 2] have repeatedly demonstrated that myocardial hypertrophy is frequently found with coronary artery disease especially in the setting of preexisting hypertension and congestive heart failure In the pathologic study of Ellis and co workers [2] who excluded cases with hypertension it was observed that cardiomegaly can occur in coronary artery disease even in the absence of congestive heart failure Cardiac hypertrophy was present in 43% of patients with prior myocardial infarction and no history of congestive heart failure In 17% of their cases cardiac hypertrophy was observed even in the absence of a prior myocardial infarction or congestive heart failure indicating as suggested by Mallory and co workers that coronary atherosclerosis by itself may stimulate cardiac hypertrophy Experimental studies in the rat reported by Norman and Coers have demonstrated that ligation of the left descending artery can result in hypertrophy of the left ventricle after 12 weeks Quantitative angiocardiographic studies have demonstrated that ischemic heart disease is commonly associated with increased left ventricular mass Furthermore such studies suggest that the increased left ventricular mass is related to the severity of the coronary artery disease In our study group 47% of patients with ECG LVH had triple vessel disease compared to 32% in the age sex matched controls Pech and co workers[*] speculated that the reparative process after hypoxic necrosis may result in compensatory hypertrophy of the remaining myocardium

Whether or not such changes in the left ventricular myocardium as discussed above can explain ECG LVH in patients with coronary artery disease and no preexisting hypertension is only speculative Interestingly those patients with ECG LVH and no hypertension had a similar Romhilt Estes point score for ECG LVH when compared to patients with hypertension Furthermore a comparison of left ventricular function in these two ECG LVH subgroups revealed no significant differences in the parameters evaluated However the most striking finding was the higher frequency ($p < 0.05$) of main left coronary artery disease in the nonhypertensive ECG LVH group (29%) as compared to the hypertensive ECG LVH group (7%) In a prior report by Cohen and Gorlin [31] the frequency of ECG LVH in patients with main left coronary disease was observed to be 9 6% which is more than twice the frequency (3 9%) we have noted in over 1 000 selected patients with documented ischemic heart disease Furthermore long term follow up of patients with main left coronary artery disease indicated that ECG LVH adversely affects the prognosis [33] It is tempting to speculate that the ominous prognosis associated with ECG LVH may in part be related to the excessive high frequency of main left coronary artery disease observed in this nonhypertensive ECG LVH subgroup

Combining ECG LVH and the presence of left atrial enlargement further defines patients with

Comparison of the inotropic action of digitalis and isoproterenol in younger and older individuals

Dennis V Cokkinos
George D Tsartsalis
Elias T Heimonas
Constantine D Gardikas
Athens Greece

Digitalis and isoproterenol both increase myocardial contractility and are used clinically for the support of the failing myocardium

There has been much discussion about the use of digitalis in the elderly It is well known that older individuals even when they do not present with any definite abnormalities differ functionally from their younger peers[1] Specifically renal function and creatinine clearance deteriorate with age This together with a decrease in muscular mass account for prolongation of digoxin half life and diminution of the volume of distribution which renders older individuals susceptible to digoxin overdosage In many studies[3] increased incidence of digitalis intoxication has been observed in the elderly This however has not been substantiated in more recent prospective studies Some clinicians have discontinued digitalis in elderly persons without documenting any difference in their cardiovascular status Similarly Starr and Luchi could not discern any positive inotropic effect of digitoxin in elderly women using the force ballistocardiogram It is interesting however that no actual clinical study exists in which the inotropic action of digitalis has been compared in younger and older individuals

We undertook to study the action of digitalis in persons younger and older than 60 years of age by the use of systolic time intervals This technique has been employed quite often for the evaluation of the action of digitalis on the myocardium[1] We also employed the same technique to assess the inotropic action of isoproterenol on the cardiac function of older people In a recent study Lakatta and associates[3] found that the myocardium of aged laboratory animals is less sensitive to catecholamines than that of younger ones

Patients and methods

1 *Digitalis study* Two groups of individuals were compared In Group A 10 were male and were female Ages ranged from 15 to 5? years (mean 34 3) In group B (15 males and females) ages ranged from 60 to 76 years (mean 65 3) All individuals in both groups were judged to be free of overt heart disease by clinical electrocardiographic and radiologic evaluation

In both groups the following systolic time intervals (STI) were measured in the basal state and supine position between 8 00 to 10 A M —electromechanical systole (QS 2) left ventricular ejection time (LVET) and pre-ejection period (PEP) the heart rate (HR) corrected indices of these intervals (QS, LVET, PEP were also estimated The PEP/LVET and PEP, LVET, ratios were also calculated The PEP LVET ratio was also corrected for HR according to the regression equations formed by our group and was termed the c(PEP/LVET) ratio According to these equations c(PEP/LVET) = PEP LVET + 0 00168 HR

After the initial study 1 2 mg deslanoside (

HR heart r te D desl nos de C ± S.E.M
Only signific t d ff rences ar des gn ted

was given intravenously to all individuals and the STI were measured 60 minutes later. By this time this drug has reached a peak effect.

2 Isoproterenol study

Group A. In 15 individuals (four males, 11 females) aged 22 to 42 years (mean 33.3) an intravenous infusion of 5% glucose was started. 30 minutes later the STI were calculated and isoproterenol was infused at a rate of 2 μg/minute for 5 minutes.[11] Thirty seconds after the end of the infusion STI were measured again.

Group B comprised 15 individuals (14 males, one female) aged 60 to 75 years (mean 67.7). The same procedure as in Group A was followed.

The differences in HR, QS$_I$, LVET$_I$, PEP, PEP$_I$, PEP/LVET, PEP$_I$/LVET$_I$ and c(PEP/LVET) before and after deslanoside or isoproterenol were compared by the paired t test. We included PEP in both its rate corrected and uncorrected forms because in contrast to QS or LVET it does not appreciably change with HR alterations.

Results

1 Digitalis study (Table I)

a. Before administration of the drug there was no difference in heart rate or systolic time intervals between Groups A and B.

b. In both groups after deslanoside a decrease in HR was observed together with shortening of the QS$_I$, LVET$_I$, PEP and PEP$_I$. The PEP/LVET, PEP$_I$/LVET$_I$ and c(PEP/LVET) ratios did not change appreciably.

The changes seen with deslanoside administra

LVET did not significantly change Thus our observations probably represent a real difference and correspond to the differences found in animals[14] We do not know whether any practical significance could be ascribed to this finding However it is possible that the therapeutic value of catecholamines is narrower in older than in younger individuals since the increases in oxygen requirements produced by these agents are not accompanied by a concomitant increase in stroke volume

Groups A and B of the isoproterenol study were not completely comparable Group B comprised more men than women while the opposite was true of Group A Perhaps the difference in base line heart frequency can be attributed not only to age which is associated with a decrease in heart rate but to sex as well women usually manifesting higher heart rates than men Still if this difference in any way can be ascribed to greater sympathetic activity in Group A this should render our results even more significant as isoproterenol would be expected to exert a smaller influence in Group A

Summary

The positive inotropic effects of digitalis (deslanoside C 1 2 mg intravenously) and isoproterenol (2 μg/minute intravenously) were compared in two groups of younger and older individuals using the systolic time interval method

Both groups responded in a completely comparable way to deslanoside C However after isoproterenol administration the LVET of the older group was significantly shortened Consequently the PEP/LVET ratio did not change significantly This difference is attributed to a lesser increase of the stroke volume in the older group

ion were quite similar in the two groups (Fig 1)

2 Isoproterenol study (Table II)

a Before administration of the drug HR was significantly higher in Group A ($p < 0.001$ Fig 2)

b After isoproterenol the HR increase was similar in both groups QS , PEP and PEP, also were equally shortened The LVET, did not change significantly in Group A but was significantly shortened in Group B ($p < 0.001$) The PEP/LVET and PEP,/LVET, ratios decreased significantly only in Group A The c(PEP/LVET) *ratio diminished at the* $p < 0.001$ *level in* Group A but only at the $p < 0.05$ level in Group B Moreover the percent diminution of all three ratios was significantly greater in Group A Fig 2)

Discussion

From our results it can be seen that digitalis exerts comparable *inotropic effects on the myo*cardium of younger and older individuals Our findings are similar to those of previous authors Thus Weissler and Schoenfeld found that decreases in QS , and PEP, were more significant that LVET, Carliner and associates found significant changes of QS , PEP PEP, and PEP/LVET with maintenance digoxin while Hoeschen and Cuddy found changes in QS and LVET only but not in PEP or PEP/LVET In patients with transvenous pacemakers in whom rate correction was not necessary we found a significant decrease in QS and PEP only The conclusion of most authors is that QS , is the most sensitive index *of digitalis action on systolic time intervals* followed by PEP while LVET and PEP/LVET changes are variable Thus although we did not try elegant digitalization we can say that *digitalis has a definite place in the treatment of* cardiac failure in the elderly Of course provision must be made for the greater susceptibility of older individuals for toxic accumulation of the *drug We did not measure drug levels in the* serum an assay difficult with deslanoside C but the dose we employed is one used quite often clinically Our findings are at variance with those *very recently* reported by Guarnieri and colleagues who found that the heart of aged rats was less sensitive to ouabain than that of younger ones However the conditions of the two studies were completely different

We are intrigued by our results with isoproterenol It is postulated that catecholamines affect the LVET in two diverse directions—the contraction time is abbreviated thus the LVET tends to shorten while the stroke volume is augmented tending to prolong the ejection time We assume that in the aged individuals the stroke volume did not increase appreciably subsequently the PEP/

LVET did not significantly change Thus our observations probably represent a real difference and correspond to the differences found in animals[13] We do not know whether any practical significance could be ascribed to this finding However it is possible that the therapeutic value of catecholamines is narrower in older than in younger individuals since the increases in oxygen requirements produced by these agents are not accompanied by a concomitant increase in stroke volume

Groups A and B of the isoproterenol study were not completely comparable Group B comprised more men than women while the opposite was true of Group A Perhaps the difference in base line heart frequency can be attributed not only to age which is associated with a decrease in heart rate but to sex as well women usually manifesting higher heart rates than men Still if this difference in any way can be ascribed to greater sympathetic activity in Group A this should render our results even more significant as isoproterenol would be expected to exert a smaller influence in Group A

Summary

The positive inotropic effects of digitalis (deslanoside C 1 2 mg intravenously) and isoproterenol (2 μg/minute intravenously) were compared in two groups of younger and older individuals using the systolic time interval method

Both groups responded in a completely comparable way to deslanoside C However after isoproterenol administration the LVET of the older group was significantly shortened Consequently the PEP/LVET ratio did not change significantly This difference is attributed to a lesser increase of the stroke volume in the older group

abry s disease an inherited glycosphingolipid torage disease results from the defective activity f the lysosomal hydrolase alpha galactosid se A The major glycosphingolipid substrate rihexosyl ceramide accumulates in plasma and he lysosomes of the kidneys heart and vasculai ndothelium [1] The major clinical manifestations of this sex linked disease—angiokeratoma acro paresthesias myocardial and cerebral infarction and renal failure—result from progressive sub trate deposition in endothelial cells and eventual occlusion of small arterioles Deposition of tri exosyl ceramide in the myocardium and cardiac conduction system can lead to thickening of ventricular walls and arrhythmias [4] Abnormali ies of the mitral and aortic valve leaflets have also been described Findings from the physical examination electrocardiogram and chest roent genogram may not indicate the full extent of cardiac involvement The sensitive detection of uch involvement may be of prognostic value in evaluation of these patients

Since echocardiography may provide a means to assess noninvasively the presence and natural history of cardiac involvement in patients with Fabry s disease a prospective echocardiographic study was undertaken in hemizygous affected males and heterozygous carrier females of this X linked disease Echocardiographic findings of patients with Fabry s disease have not been pre viously described

Materials and methods

Thirty two patients with Fabry s disease 25 hemizygotes and seven heterozygotes seen at the University of Minnesota form the basis of this report Each hemizygote had typical clinical find ings of Fabry s disease and was shown to lack detectible levels of alpha galactosidase A in plas ma leukocytes and/or fibroblasts Heterozygotes had intermediate alpha galactosidase A levels and/or elevated urinary trihexosyl ceramide lev els The patients were examined for evidence of cardiac disease or hypertension

Echocardiograms were performed with the transducer in the third or fourth intercostal space near the left sternal border and perpendicular to the chest wall while recording the mitral valve anterior leaflet Recordings were made on a Smith Kline Instruments ultrasonoscope inter faced with a strip chart recorder The echocardio grams were measured with calipers where the technical quality of the recording was adequate for evaluation End diastolic measurements were made at the time of the onset of the QRS complex End systolic measurements were made at the time of aortic valve closure or maximal excursion of the left ventricular posterior wall Measurements were made utilizing leading edge

Reply

To the Editor

Doctors Self and Vanderbush have shown that equipment and labor inputs for the *intermittent method of heparin administration* may be quite a bit less than for the continuous method This is an undeniably pertinent fact bearing on the choice of a preferred method

Our study suggested that neither method had a clear advantage in reducing risk of serious hemorrhage The small numbers of patients in this study limits the certainty with which this conclusion is justified Nevertheless, until convincing evidence of less efficacy or greater risk is presented we would agree that it is quite reasonable to recommend the intermittent method on the basis of economic considerations

† = full expression in heterozygote

dimension of our 11 patients in this same age range (50.5 mm) was not statistically different. The diastolic left ventricular dimension was measured in six heterozygotes with a mean of 43.5 mm.

The left ventricular shortening fraction was calculated in 22 hemizygous patients. The nine patients under 26 years had a shortening fraction of 0.33 ± 0.05 (mean ± standard error of the mean), not significantly different from the 13 older patients (0.33 ± 0.02 mean ± standard error of the mean). Nor was this different from the mean value of 0.34 found by Gertsenblith and associates in 37 normal adults between 25 and [illegible] years of age. Shortening fraction was calculated in six heterozygotes with a mean of 0.35.

The ratio of diastolic ventricular septal thickness to left ventricular posterior wall thickness was greater than 1.3 in two of the 21 normotensive hemizygotes and in two of six heterozygotes. However three of these four patients had a ventricular septal thickness of 10 mm or less. Only the clinically affected heterozygote had an abnormally thick ventricular septum with a ra[illegible]

sent in one hemizygote who also had an apical late systolic murmur Another patient with auscultatory evidence of aortic regurgitation showed diastolic flutter of the mitral valve leaflets Eccentric closure of the aortic valve was recorded in three hemizygotes who also had increased aortic root dimensions

The aortic root dimension was measured in each hemizygote In the nine patients less than 26 years of age the aortic root dimension was 33 2 ± 1.2 mm (mean ± standard error of the mean) and in two (22%) it was greater than 37 mm (the maximum reported by Feigenbaum in normal adults) In the 16 hemizygotes older than 26 years the aortic root dimension was 38 1 ± 1 2 mm (mean ± standard error of the mean see Fig 2) and 12 (75%) showed a dimension greater than 37 mm This difference in aortic root dimensions between the age groups was statistically significant ($p < 0.01$) Gertsenblith and associates found a mean aortic root diameter of 30 9 mm in 45 adults between 25 and 44 years of age The mean aortic root dimension of our 15 hemizygous patients between 25 and 44 years was 38 6 mm a statistically significant difference from normal ($p < 0.001$) When the aortic root dimension was compared to body surface area as a root function the correlation ($R = 0.34$) was not statistically significant ($p > 0.05$)

The echocardiographic aortic root dimension was measured in six of the heterozygotes and was less than 37 mm in each

The diastolic left ventricular posterior wall thickness was measured from the echocardiograms of 21 normotensive hemizygous patients In the patients under 26 years of age the left ventricular posterior wall thickness (9 6 ± 1 3 mm mean ± standard error of the mean) was not significantly different ($p > 0.05$) from the 12 patients older than 26 years (12 4 ± 0 7 mm mean ± standard error of the mean see Fig 3) Whereas two of the nine younger patients (22%) had a diastolic left ventricular posterior wall thickness greater than 11 mm (the maximum thickness reported by Feigenbaum in normal individuals) eight of the 12 older patients (67%) had a measurement greater than 11 mm Gertsenblith and associates[7] reported the echocardiographic diastolic left ventricular wall thickness in 33 adults between 25 and 44 years of age and found a mean of 8 7 mm The mean thickness in our 12 normotensive hemizygotes in this same age

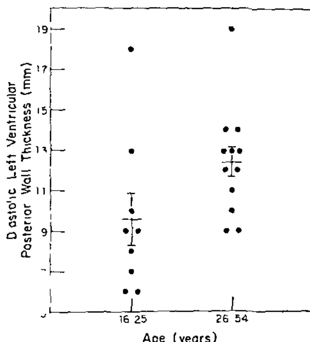

Fig 3 Distribution of echocardiographic left ventricular wall thickness in patients with Fabry's disease *Lines and intervals* indicate mean ± one standard error of the mean *The stippled area* indicates the expected range of normal from Feigenbaum

range was 11 9 mm a statistically significant difference ($p < 0.001$) When the left ventricular posterior wall thickness was compared to body surface area as a linear function the correlation ($R = 0.42$) was not statistically significant ($p > 0.05$) The echocardiographic diastolic left ventricular posterior wall thickness was measured in each heterozygote and was greater than 11 mm in two of the seven

Systolic and diastolic left ventricular internal dimensions were measured from the echocardiograms of 22 hemizygous patients Of the three patients in whom these measurements were not made two were excluded because of paradoxical ventricular septal motion and the third was excluded because the quality of the echocardiogram was technically inadequate The diastolic left ventricular dimension in the nine patients under 26 years (47 8 ± 1 11 mm mean ± standard error of the mean) was not significantly different from the 13 patients over 26 years of age (50 5 ± 2 58 mm mean ± standard error of the mean) Gertsenblith and associates found a diastolic left ventricular dimension of 51 8 mm in 37 adults between 25 and 44 years of age The mean

wall thickness probably reflect deposition of glycosphingolipid in the myocardium

The recent demonstration of biochemical effects of enzyme replacement in Fabry s disease increases the importance of a sensitive noninvasive technique for the assessment of effects of this therapeutic approach[9] Should the disease prove to be reversible, the response to this treatment could be monitored by echocardiographic evidence of regression of abnormal thickness of the left ventricular posterior wall Changes in the aortic root dilatation would be less likely to occur In addition the development of increasing left ventricular wall thickness or aortic root dimension while on replacement therapy would be significant While we detected echocardiographic abnormalities in our patients we do not have sufficient serial studies to determine if echocardiography will be sensitive enough to detect changes in response to therapy

Summary

Fabry s disease results from deficient activity of the enzyme alpha galactosidase A Cardiac abnormalities result from glycosphingolipid deposition in the myocardium valvular tissue and vessel walls A noninvasive method to examine these abnormalities would be useful in the evaluation of patients We examined the echocardiograms of 32 patients 25 hemizygous and seven heterozygous for Fabry s disease

The aortic root diameter was measured in each hemizygote In nine patients under 26 years it was 33 2 ± 1 2 mm and in two it was dilated In 16 patients over 26 years it was 38 8 ± 1 2 mm ($p < 0\ 01$) and in 12 it was dilated The left ventricular posterior wall was measured in the echocardiogram of 21 normotensive hemizygotes The difference in thickness between nine patients under 26 years (9 6 ± 1 3 mm) and 12 patients over 26 years (12 4 ± 07 mm) was not statistically significant Only two of the nine younger patients had left ventricular wall thickness greater than normal compared to eight of the 12 older patients The mean left ventricular shortening fraction of 22 hemizygous patients was normal One hemizygote had echocardiographic evidence of mitral valve prolapse

Four of the seven heterozygotes had normal echocardiograms Among the other three one had increased left ventricular wall thickness a second had disproportionate ventricular septal thickness and a third had both abnormalities. The echocardiographic aortic root size was normal in each heterozygote

Abnormal echocardiographic findings were more common in older hemizygous patients, a distribution similar to that of the age of onset of cardiac dysfunction Increased left ventricular wall thickness probably reflects glycosphingolipid deposition in the myocardium Dilatation of the aortic root may result from degenerative changes of the aortic media Abnormalities of mitral valve echoes were uncommon

greater than 1 3 There was no evidence of systolic anterior motion of the mitral valve or midsystolic closure of the aortic valve on the echocardiograms of any patients

Discussion

Cardiac involvement has long been recognized in Fabry's disease[2] Autopsy studies have described ballooning or interchordal hooding of mitral valve leaflets thickening of the ventricular wall and calcification of the aortic valve leaflets[2] Occasionally abnormalities of the tricuspid valve have also been noted[3] Electron microscopic studies have also shown extensive degeneration of the walls of the ascending aorta These reports have been confined to isolated autopsy cases and the spectrum of involvement in a large group of patients with Fabry's disease has not been reported

Echocardiography allows noninvasive evaluation of patients with Fabry's disease Although chordae tendineae have been described as normal the interchordal hooding in some patients with Fabry's disease[3] is similar to that described in the myxomatous mitral valve[6] Thickening of mitral valve leaflets or a pattern of mitral valve prolapse might be detected on the echocardiogram Thickening of ventricular walls can be easily measured by this technique In addition if degeneration of the ascending aorta results in dilatation this might also be measured from the echocardiogram

A single hemizygote had both an apical late systolic murmur and pansystolic mitral valve prolapse on the echocardiogram Evidence of abnormalities of the mitral valve were not found on the echocardiograms of our other Fabry's patients either heterozygotes or hemizygotes If the abnormality of the mitral valve leaflets described in some autopsy reports in patients with Fabry's disease is common the M mode echocardiogram did not detect it

The aortic root dimension measured by echocardiography increased with age There was a higher incidence of an abnormal aortic root dimension in our older patients and a statistically significant difference in the means of aortic root dimension between the two age groups

The difference in mean left ventricular myocardial thickness between younger and older hemizygous patients was not statistically significant However the incidence of an abnormally thick left ventricular wall was greater in the older patients and their wall thicknesses were greater than a comparable normal population Left ventricular function as estimated by the shortening fraction was normal in our patients

Comparison of our patients with the normal range for echocardiographic aortic root dimension and left ventricular wall thickness described by Feigenbaum seems justified as his subjects were similar to ours in age range (13 to 54 years) and body surface area 1 3 to 2 2 M^2)[6] Aging alone cannot explain the greater aortic root dimensions and left ventricular wall thicknesses in our older hemizygous patients When compared to age matched subjects reported by Gertsenblith and associates[7] our hemizygous patients as a group had greater aortic root dimension and left ventricular wall thickness Neither aortic root dimension nor left ventricular wall thickness correlated with body surface area and the differences in our younger and older patients cannot be explained by differences in patient size

We had only a small number of echocardiograms in heterozygous patients Although one of our seven heterozygous patients was clinically affected each had normal mitral valve echoes and normal aortic root dimensions The left ventricular posterior wall thickness was increased on the echocardiograms of two of the heterozygous patients only one of whom was clinically affected (this latter patient also had disproportionate ventricular septal thickening)

The M mode echocardiogram allowed us to detect abnormalities of aortic root dimension and left ventricular wall thickness in many but not all of our patients with Fabry's disease Abnormal echocardiographic findings were more common in older hemizygous patients and this distribution is similar to the common onset of cardiac dysfunction in the third and fourth decade of life The degenerative changes described by Becker and associates[3] in the aortic media may explain the increased aortic root dimensions in some patients Dissecting aneurysms however have not been a problem in our patients nor has this complication been reported by others The absence of mitral valve abnormalities on the echocardiogram may mean that structural abnormalities in mitral valve leaflets are not common in patients with Fabry's disease or that the changes are not significant enough to be detected by echocardiography Increases in left ventricular

Table 1 Background data on patients in the study

Extent of disease	Number of patients	Mean age	Reason for catheterization: Typical angina pectoris	Atypical angina pectoris	Other	Resting ECG: Normal	Abnormal	Infor- on ECG
0 vessel	13	48	6	6	1	10	3	0
1 vessel	14	51	7	5	2	4	10	5
2 vessel	15	51	9	3	2	3	12	1
3 vessel	8	50	6	1	1	2	6	3

changes in position[10-12] patients were monitored at the beginning of each ambulatory ECG recording in six standardized positions (prone supine left side right side sitting and standing) ECG s were also recorded with hyperventilation and Valsalva maneuver neither of which caused any ECG changes in the group of patients studied Calibration signals were provided at the beginning of each recording by a millivolt calibrator (Del Mar Avionics Irvine Ca, Model No 456)

ECG lead system After preparation of the skin Exerstress (Del Mar Avionics Irvine, Ca) electrodes were firmly attached at the positions of CC5 (positive electrode fifth intercostal space anterior axillary line on the left negative electrode in corresponding position on the right) and modified aV_F (positive electrode below the xyphoid process negative electrode beneath the mid left clavicle) The ground electrode was positioned on the right flank The modified aV_F was found to closely resemble aV_F on scalar ECG s in 20 patients in whom both of these leads were placed and compared In this group the R/S ratio of modified aV_F was 82% of the R/S ratio in scalar aV_F Lead CC5 has been shown in the past to closely resemble Lead V_5 on scalar ECG s[1]

Ambulatory ECG tapes were evaluated using a dynamic electrocardioscanner (Del Mar Avionics Irvine Ca Model No 660A) Average heart rate in each patient was determined by the total number of beats per 24 hours divided by 1 440 minutes per day If any artifacts were noted during the scanning the beats counted and time elapsed during that period were excluded from analysis Random recordings each lasting six seconds were obtained at 15 minute intervals during the day (97 recordings per 24 hours) Each random recording was analyzed for ST segment deviations and considered positive if the ST segment was deviated more than 1 mm greater than any positional ST segment change noted on baseline recordings persisting for at least 0 08 sec from the J point in at least three consecutive beats This criterion is commonly used in exercise testing[14]

In addition the extent of ST segment deviation on the ambulatory ECG was compared with that of simultaneously recorded scalar ECG s during exercise testing in 23 different patients during another study ST segment deviations were within 0 25 mm by both methods

Times of day of all ST segment deviations were noted and were compared with entries in the patient s diaries which were completed very compulsively by the majority of study patients. ST segment deviations in association with symptoms or occurring five minutes before or after symptoms were excluded from analysis and were considered separately The number of recordings with silent ST segment deviations was divided by the total number of recordings during the 24 hours to determine the percentage of observations in which silent ST segment deviations occurred Heart rate during all deviations was recorded The extent of ST segment deviations was measured independently by two observers without knowledge of angiographic findings

Angiography Coronary angiography and ventriculography were performed by using the Sones technique[5] Angiograms were analyzed in two views and were considered to reveal significant coronary artery disease if any major vessel had greater than 70% luminal diameter narrowing in one plane or greater than 50% luminal diameter narrowing in two planes Patients were then divided into groups with one two and three vessel disease Patients with normal coronary arteries and those with less than 70% luminal diameter narrowing in any major artery were considered to have zero vessel disease The results showed no difference between the subgroups of patients making up the group with zero vessel

Silent ST segment deviations and extent of coronary artery disease

The clinical diagnosis of myocardial ischemia in ambulatory patients is usually based on a history of typical angina pectoris However myocardial ischemia occurs without pain and painless ST segment deviation as sometimes occurs during exercise testing may indicate the presence of asymptomatic coronary artery disease There have been relatively few reports to delineate the prevalence of clinically silent ST segment deviations in ambulatory patients during routine activities rather than during exercise testing The significance of such changes is as yet unknown and it is unclear to what extent they occur in apparently normal patients

We studied 50 patients both with and without coronary artery disease as demonstrated by coronary angiography to determine the extent of silent ST segment deviations during routine daily activity We determined the relationship of the latter to the presence and severity of coronary artery disease and to ventricular function and heart rate

Methods

Patient population After obtaining informed consent we studied 50 patients all of whom had cardiac catheterization and left ventricular angiography to evaluate typically ischemic chest pain (27 patients) or atypical chest pain (16 patients) or to evaluate coronary anatomy after myocardial infarction syncopal episodes or episodic dyspnea (seven patients) Atypical chest pain was defined as a sticking or stabbing chest pain which was not regularly precipitated by exertion The sample population consisted of 39 men ages 31 to 68 and 11 women ages 39 to 53 Patients with a left bundle branch block valvular lesion metabolic abnormality (abnormal calcium or potassium levels thyroid disease) or inability to ambulate were excluded Patients with mitral valve prolapse and those with hypertrophic cardiomyopathy were also excluded Twenty six patients were receiving propranolol in doses of 40 to 160 mg per day (average dose 100 mg daily) One patient was receiving propranolol in a dose of 320 mg per day and 25 patients were receiving either nitroglycerin or isosorbide dinitrate in doses of 10 to 40 mg per day at the time of the study Five patients had received digoxin 0 25 mg per day until the day of the study

Monitoring periods Each patient was monitored with a two channel ambulatory ECG (Del Mar Avionics Irvine Ca Model No 445) for 24 hours before or after cardiac catheterization During monitoring patients were instructed to perform their routine daily activities and to keep thorough diaries detailing stressful or unusual activities times of meals rest periods and any experience of discomfort To determine any changes in the ST segment which occurred due to

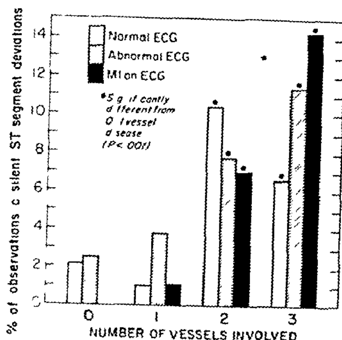

Fig 2 Effect of the resting ECG on the correlation of the prevalence of silent ST segment deviations and the extent of coronary artery disease *Clear bars* represent normal resting ECG s *hatched bars* represent abnormal resting ECG s and *black bars* represent old myocardial infarction on the resting ECG Silent ST segment deviations correlated with the extent of coronary artery disease regardless of the resting ECG There was no significant difference in the prevalence of silent ST segment deviations within each class of coronary disease regardless of the resting ECG

typical and atypical chest pain were analyzed separately and this variable did not affect results

Silent ST segment deviations and resting ECG Patients in each group presenting with normal and abnormal resting ECG s as well as those with old myocardial infarction on resting ECG are shown in Table I When patients with normal and abnormal resting ECG s were analyzed separately this variable was found not to affect results (Fig 2)

Silent ST segment deviations and pharmacologic therapy The number of patients receiving propranolol is shown in Table II As might be expected since more severely ill patients were more likely to receive treatment this number increased with severity of disease Propranolol therapy might be expected to decrease the occurrence of silent ST segment deviations In this study propranolol did not significantly affect the relationship between prevalence of silent ST segment deviations and the extent of coronary artery disease ($p > 0.05$) (Fig 3) Though there were numerical differences in the prevalence of silent ST segment deviations between patients with and without propranolol within each group this difference was not statistically significant Patients being treated with propranolol had an average heart rate of 67 beats per minute while those without propranolol averaged 72 beats per minute Propranolol may never have been given to full beta blockade

Table II also shows the percentage of patients in each disease category who were receiving nitrates Nitrate therapy did not affect the prevalence of ST segment deviations (Fig 3) Numerical differences in the prevalence of silent ST segment within each group were found for patients with and without nitrate therapy but these differences were not statistically significant We did not attempt to alter drug regimens of patients in our study and therefore patients were not receiving nitrates in any standard protocol

Five patients were receiving digitalis preparations and these patients were only in the two and three vessel disease groups Although dig is may clearly influence ST segments during exercise testing causing false positive tests the differences in the percent of observations in 24 hours with silent ST segment deviations between groups was not influenced when patients receiving digitalis were excluded

Silent ST segment deviations and left ventricular function There was no relationship between silent ST segment deviations and the presence and degree of wall motion abnormalities Normal or abnormal ejection fraction was also unrelated

Silent ST segment deviation and heart rate Increased heart rate was defined here as 10 beats per minute above the average daily heart rate In the zero vessel disease group 60% of silent ST segment deviations occurred at increased heart rates and therefore may have been rate rel However in the one two and three-vessel disease groups only 34% 7% and 25% respectively of silent ST segment deviations occurred at heart rates higher than 10 beats per minute above the average daily heart rate Therefore the majority of ST segment deviations did not appear to be rate related

ST segment deviations associated with pain No patient with zero vessel or one-vessel disease had any observations of ST segment deviation which were associated with pain as noted in the patient s diary Six percent of observations of ST

Table II Numbers of patients displaying silent ST segment deviations and receiving medications

Extent of disease (no of pts)	*Number displaying silent ST segment deviations*	*Number receiving propranolol*	*Number receiving nitrates*
0 vessel (13)	5	3	6
1 vessel (14)	7	6	5
2 vessel (15)	15	12	10
3 vessel (8)	8	7	5

disease Angiographic interpretation was performed without knowledge of the results of ambulatory ECG analysis

For evaluation of ventricular function segmental motion analysis[16] of the left ventriculogram was made and the resting ejection fraction was determined Wall motion abnormalities were expressed as being dyskinetic akinetic and hypokinetic and the percent of the perimeter of the left ventricular silhouette with abnormal wall motion was determined

Statistical analysis The patients were divided into four groups zero one two and three vessel disease The percent of silent ST segment deviation per patient was recorded and transformed using an arcsin transformation Comparisons among the four groups were made using the analysis of variance and Duncan's multiple range procedure All statistical tests were done using a P level of < 0.05

Results

The number of patients in each group their ages reason for catheterization and resting ECG are shown in Table I The percentage of patients who displayed any silent ST segment deviations is shown in Table II Thirty eight percent of patients with nonobstructive disease and 50% of patients with one vessel involvement displayed these changes All patients with two and three vessel disease had silent ST segment deviations

Fig 1 shows for each group the percentage of observations in which ST segments shifted This percentage increased with the increasing extent of coronary artery disease The group with zero vessel disease had silent ST segment deviations an average of 2.2 ± 1.0% of observations in 24 hours one vessel disease had silent ST segment deviations 2.9 ± 1.8% of observations in 24 hours

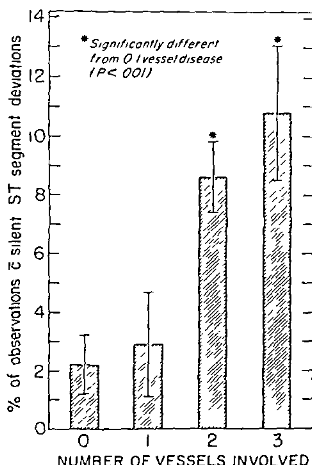

Fig 1 Correlation of silent ST segment deviations with the extent of coronary artery disease *Hatched bars* represent the percentage of observation with silent ST segment deviations on the ambulatory ECG for each grade of coronary artery disease Note how this percentage increases with the extent of coronary artery disease See text for further discussion

two vessel disease 8.2 ± 1.0% of observations in 24 hours and three vessel disease 10.1 ± 2.4% of observations in 24 hours The difference in the percent of observations with silent ST segment deviations during 24 hours between zero and one vessel disease groups when compared with the two and three vessel disease groups was significant ($p < 0.001$) while other differences were not

The following factors had no influence on the correlation between percent of observations of silent ST segment deviations and the extent of coronary artery disease

Silent ST segment deviations and precatheterization symptoms Table I shows the occurrence of typical and atypical chest pain with varying extent of coronary artery disease Patients with

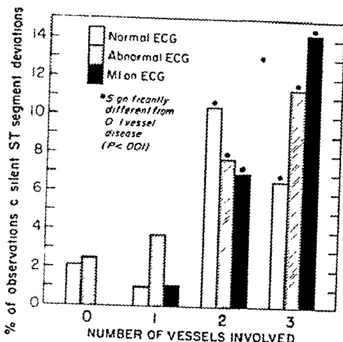

Fig 2 Effect of the resting ECG on the correlation of the prevalence of silent ST segment deviations and the extent of coronary artery disease *Clear bars* represent normal resting ECG s *hatched bars* represent abnormal resting ECG s and *black bars* represent old myocardial infarction on the resting ECG Silent ST segment deviations correlated with the extent of coronary artery disease regardless of the resting ECG There was no significant difference in the prevalence of silent ST segment deviations within each class of coronary disease regardless of the resting ECG

typical and atypical chest pain were analyzed separately and this variable did not affect results

Silent ST segment deviations and resting ECG Patients in each group presenting with normal and abnormal resting ECG s as well as those with old myocardial infarction on resting ECG are shown in Table I When patients with normal and abnormal resting ECG s were analyzed separately this variable was found not to affect results (Fig 2)

Silent ST segment deviations and pharmacologic therapy The number of patients receiving propranolol is shown in Table II As might be expected since more severely ill patients were more likely to receive treatment this number increased with severity of disease Propranolol therapy might be expected to decrease the occurrence of silent ST segment deviations In this study propranolol did not significantly affect the relationship between prevalence of silent ST segment deviations and the extent of coronary artery disease ($p > 0.05$) (Fig 3) Though there were numerical differences in the prevalence of silent ST segment deviations between patients with and without propranolol within each group the difference was not statistically significant Patients being treated with propranolol had an average heart rate of 67 beats per minute while those without propranolol averaged 7? beats per minute Propranolol may never have been given to full beta blockade

Table II also shows the percentage of patients in each disease category who were receiving nitrates Nitrate therapy did not affect the prevalence of ST segment deviations (Fig 3) Numerical differences in the prevalence of silent ST segment within each group were found for patients with and without nitrate therapy but these differences were not statistically significant We did not attempt to alter drug regimen of patients in our study and therefore patients were not receiving nitrates in any standard protocol

Five patients were receiving digitalis preparations and these patients were only in the two and three vessel disease groups Although digitalis may clearly influence ST segments during exercise testing causing false positive test the differences in the percent of observations in 24 hours with silent ST segment deviations between groups was not influenced when patients receiving digitalis were excluded

Silent ST segment deviations and left ventricular function There was no relationship between silent ST segment deviations and the presence and degree of wall motion abnormalities Normal or abnormal ejection fraction was also unrelated

Silent ST segment deviation and heart rate Increased heart rate was defined here as 10 beats per minute above the average daily heart rate In the zero vessel disease group 60% of silent ST segment deviations occurred at increased heart rates and therefore may have been rate related However in the one two and three vessel disease groups only 34% 7% and 25% respectively of silent ST segment deviations occurred at heart rates higher than 10 beats per minute above the average daily heart rate Therefore the vast majority of ST segment deviations did not appear to be rate related

ST segment deviations associated with pain No patient with zero vessel or one-vessel disease had any observations of ST segment deviations which were associated with pain as noted in the patient s diary Six percent of observations of ST

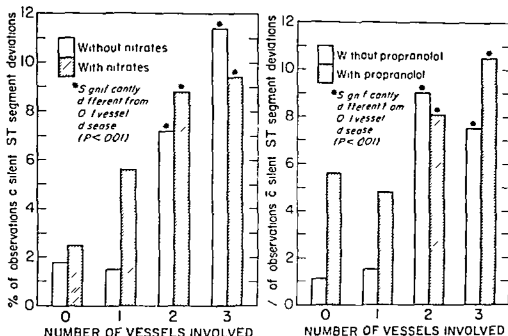

Fig 3 Lack of influence of propranolol and nitrate therapy in the doses used on the correlation of the prevalence of silent ST segment deviations with the extent of coronary artery disease *Vertical axis* represents the percentage of observations in 24 hours with ST segment deviations *Hatched bars* represent patients receiving medications (see text for dose) Silent ST segment deviations correlated with the extent of coronary disease regardless of propranolol or nitrate therapy in these doses. Though there were numerical differences in the prevalence of ST segment deviation between patients with and without medications within each class of disease the differences were not statistically significant

segment deviation in the two vessel disease group and 3% of observations in the three vessel disease group were associated with pain and these observations were excluded from analysis

Discussion

Clinically coronary artery disease usually presents with angina pectoris or with catastrophic events such as myocardial infarction or sudden death Our study suggests however that in addition to these manifestations there are regular and frequent dynamic electrocardiographic changes (ST segment deviations) which may reflect underlying recurrent myocardial ischemia as has been suggested previously[6, 9] Pain is only one of the clinically recognizable responses to ischemia and the frequency of silent ST segment deviations suggests that painless ischemia occurs frequently in patients with obstructive coronary artery disease Furthermore the frequency of these ST segment deviations on the ambulatory ECG correlates with the severity of the coronary artery disease Though no significant difference was noted between patients with nonobstructive coronary artery disease and one vessel disease or between two and three vessel disease there was a markedly significant difference ($p < 0.001$) between the zero and one and two and three vessel disease groups This difference was not influenced by the patient s symptoms resting ECG or ventricular function but only by the number of coronary arteries occluded Also since most ST segment deviations occurred at heart rates within 10 beats per minute of the average heart rate the deviations were probably not rate related

Previous studies of silent ST segment changes on the ambulatory ECG have been consistent with our observations in showing that they occur more commonly in patients with clinical coronary artery disease[6, 7] that they may have prognostic significance[7] and that they can occur during driving and sleep[6] However comparison of silent ST segment deviations on the ambulatory ECG with the extent of angiographically proven coronary artery disease has not been previously made

In studies using the ambulatory ECG it is important to properly evaluate the lead system used Ambulatory ECG systems use bipolar chest leads and differ both from conventional ECG

most false negative exercise tests occur in patients with one vessel disease.[5] Also we stress that it is not the presence of ST segment deviations but rather the total duration of ST segment deviations over 24 hours which correlates with more severe degrees of coronary disease. Ultimately though, since we are unsure of the actual cause of ST segment deviations, we cannot state why more silent ST segment deviations were not seen in patients with one vessel disease.

In the present study, there were few episodes of ST segment deviation associated with the subjective experience of pain. The use of patient diaries has certain limitations, though the importance of keeping complete records was stressed and was carried out. It is possible as well that patients voluntarily curtailed their activities because of the monitoring procedure. It must also be considered that the pharmacotherapy the patients received may have suppressed pain without altering the electrocardiographic determinants of ischemia. This may have been a function of inadequate therapy, as mentioned above.

Because painless ST segment deviations on the ambulatory ECG are relatively frequent in patients with coronary artery disease, reversal of ST segment deviations may provide a more definite end point of therapy to reverse ischemia than either relief of pain or exercise testing. This technique may also be used to evaluate drug or surgical therapy.

The occurrence of frequent silent ST segment deviations in patients with two and three vessel coronary artery disease may reflect an important underlying process that is undetectable without specific and proper testing.

Summary

Fifty patients who underwent coronary and left ventricular angiography for suspected coronary artery disease (CAD) had ambulatory ECG monitoring at a time remote from that of catheterization. After correcting for positional ST segment variation on ambulatory ECG, the amount of time that ST segments deviated more than 1 mm from baseline without corresponding angina was determined, and these results were correlated with results of angiography. Silent ST segment deviations were seen in patients without significant CAD in 2.2% of observations, but increased significantly with extent of coronary artery disease (2.9%, 8.2%, and 10.1% of observations in the one, two, and three vessel disease groups, respectively). This relationship was independent of ventricular function, resting ECG, and previous symptoms. It is concluded that silent ST segment deviations on ambulatory ECG reflect the presence and severity of coronary artery disease.

Previous clinical studies on left ventricular volumes[1-4] have shown that M mode echocardiography correlates well with angiography for patients with normal myocardial wall motion but not for those with regional myocardial dyssynergy The cube method of M mode echo utilizes only one diameter measurement and is derived from the formula for the volume of a symmetrical ellipsoid Thus inaccuracies of volume quantification should accompany any ventricular asymmetry due to regional dyssynergy

Recently techniques were developed in this laboratory for performing noninvasive cross sectional echocardiography in closed chest dogs[5] With this technique a variety of left ventricular cross sectional images may be recorded for detailed analysis of cardiac size structure and function this development represents a definite improvement over the one-dimensional measuring capabilities of M mode echocardiography

Previous cross sectional echocardiographic studies from this laboratory demonstrated that left ventricular mass in the closed chest dog[7] and left ventricular volume in the formalin fixed heart[8] may be quantified best with mathematical models incorporating short axis area measurements However the adequacy of cross sectional echocardiography for quantification of left ventricular volume in the presence of substantial ventricular asymmetry has not been investigated Thus a study of cross-sectional echocardiography was designed to investigate the influence of asymmetry on volume quantification in formalin fixed canine left ventricles Echocardiographic cross sectional images were obtained and mathematical models were utilized similar to those for in vivo studies of the left ventricle[7]

Methods

Cross sectional echocardiographic studies were performed with an electronic phased array sector scanner (Varian Associates Palo Alto CA) Features of this system include real time high resolution a 32 element transducer an 84 degree sector angle and a videotape recording rate of 30 frames per second The 84 degree sector angle facilitates recording of entire cross sections of the left ventricle in short axis or long axis orientations

Nineteen dogs were killed with an overdose of anesthetic and their hearts were removed left ventricles were separated from the rest of the heart stuffed with gauze and fixed in formalin for at least 3 days Insertion of gauze was neces

CROSS-SECTIONAL ECHOCARDIOGRAPHY
MATHEMATICAL MODELS FOR LV VOLUME

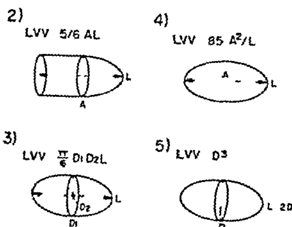

Fig 4 This figure illustrates four of the mathematic models that were utilized in this study Each formula is accompanied by a geometric figure from which the formula was derived Model 2 on the upper left shows that with endocardial area *(A)* from only one short axis cross-section and the length *(L)* from one long axis cross-section left ventricular volume may be calculated by the formula shown $V = 5/6\ AL$, which is represented by the figure shown a half cylinder half ellipsoid Model 3 on the lower left shows that with both minor axis diameters from one short axis section and left ventricular length *(L)* from a long axis section, the volume of an ellipsoid may be computed by $V = \pi/6\ D_1 D_2 L$, where D_1 = septal to lateral diameter D_2 = anterior to posterior diameter This is a standard ellipsoidal formula that has been utilized previously with cineangiography for left ventricular volume determination. With Model 4 on the upper right, the volume of an ellipsoidal figure is calculated by the standard angiographic area length formula $V = 0.85\ A^2/L$ this formula utilizes both the area *(A)* and the length *(L)* from a long axis section of the left ventricle With Model 5 on the lower right the volume of an ellipsoidal figure is calculated with the cube method formula $V = D^3$ developed specifically for M mode echocardiography D = septal lateral diameter of the left ventricle

Mathematical models

Model 1 (Fig 3) Length (L) was divided by the number of short axis sections to obtain an arbitrary height (h) for each short axis section Left ventricular volume was then calculated by a short axis reconstruction procedure using Simpson's rule based upon short axis areas (A) and heights Volume for the apical section was calculated by the formula for an ellipsoidal volume segment shown as the last two terms in the ventricular volume formula at the bottom of Fig 3 Volumes for each remaining short axis section were calculated simply by multiplying the respective area (A) of the section by height (h) Ventricular endocardial volume (V) is obtained by summation of the section volumes,

$$V = A_1 h + A_2 h + A_3 h + \frac{A_4 h}{2} + \frac{[illegible] h^3}{6}$$

Model 2 (Fig 4) The volume (V) of a cylinder may be simply calculated by multiplying the area (A) from a single left ventricular short axis section at the low papillary muscle level with the left ventricular length (L) determined from a long axis section $V = AL$ The volume of the ellipsoid is calculated from the same parameters i.e. A and L using the following derivation $V = 4/3\pi\ r_1 r_2 r_3$ for a nonprolate ellipsoid where r_1, r_2 and r_3 are the respective radii assuming $A = \pi r_1 \times r_2$ and $L = 2r_3$, $V = 2/3\ AL$ Thus the only difference between the volume formulas for ellipsoid and cylinder models is a constant (2/3) Since the left ventricle may be represented by a shape that is ellipsoidal toward the apex and cylindrical toward the base (Fig 4A *top left panel*) the volume formula for Model 2 was approximated by averaging the constants for the ellipsoid and cylinder models $V = 5/6\ AL$

Model 3 (Fig 4) The volume of an ellipsoid is calculated from the left ventricular length (L) and both minor axis diameters determined from a short axis echocardiographic section at the low papillary muscle level D_1 = septal to lateral diameter D_2 = anterior to posterior diameter The formula for the volume of an ellipsoid is $V = 4/3\ \pi\ r_1\ r_2\ r_3$ if $D_1 = 2r_1$ $D_2 = 2r_2$ and $L = 2r_3$ then $V = \pi/6\ D_1\ D_2 L$ This standard ellipsoidal formula has been utilized previously for left ventricular volume by cineangiography

Model 4 (Fig 4) Volume of an ellipsoidal figure may be calculated by the standard angiographic area length formula utilizing the area (A_L) and the length (L) both from a long axis section of the ventricle Using $V = 4/3\ \pi\ r_1\ r_2\ r_3$ one assumes $r_1 = r_2$, $r_3 = L/2$ and $A_L = \pi r_1 (L/2)$ Then $r_1 = r_2 = 2A_L/\pi L$ $V = 4/3\pi (2A_L/\pi L)^2 (L/2) = 0.85\ A_L{}^2/L$

Model 5 (Fig 4) Volume of an ellipsoidal figure may be calculated with the cube formula developed specifically for M mode echocardiography This method uses the septal to lateral diameter (D) of the left ventricle measured at the low papillary muscle level If $V = 4/3\pi\ r_1\ r_2\ r_3$ and $r_1 = r_2 = D/2$ and r_3 is assumed $= D$ then $V = D^3$

Data analysis In 19 formalin fixed left ventr

Fig 2 *A* Polaroid photograph of a typical echocardiographic long axis image from a formalin fixed left ventricle *B* A diagrammatic sketch illustrates the orientation of this image Above is the anterior wall below the posterior septum to the right is the base and to the left is the apex Length is measured from apex to base as indicated The approximate endocardial border is outlined by the *broken line*

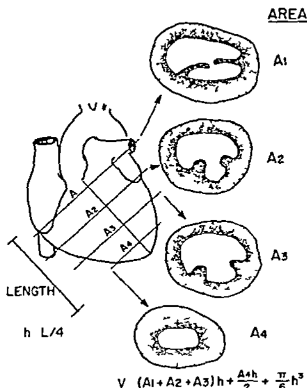

Fig 3 Sectional analysis of the left ventricle (LV) in dogs with the phased array sector scanner Short axis cross-sectional views are obtained at four to eight levels from the base to the apex Shown here are (1) mitral valve section (A1 = area of endocardial surface) (2) high papillary muscle section (A2 = area) (3) low papillary muscle section (A3 = area) (4) apical section (A4 = area) LV length *(L)* obtained from a long axis view (apex to mitral-aortic junction) is divided by the number of short axis sections to give an arbitrary height *(h)* for each section Volume *(V)* of the chamber is calculated by Simpson s rule for summation of area height for each section except the apical section the volume of which is calculated with the formula for an ellipsoidal segment

inner echo borders was found to carry smaller interobserver variability than tracing at the center of the endocardial echo Linear measurements were obtained from the cross-sectional outlines and areas enclosed within the outlines were obtained by planimetry Length of ventricles was measured in the long axis section (Fig 2) as the distance from apex to the mitral ring at the base In a previous study of two D echo in dogs left ventricular short axis diameter and area measurements in several simplified mathematic models were based on a section taken at the high papillary muscle level Formalin fixation procedures in this study resulted in some constriction of the chamber lumen at the base of the LV so that the high papillary section was not always representative of the LV Thus with formalin fixed left ventricles the short axis section at the low papillary muscle level two thirds of the distance between the base and apex was utilized for the simplified models[2]

Calibration of cross sectional echocardiographic measurements was performed from scales along the horizontal and vertical axes of the images predetermined in the system used (Varian Inc) from precise fixed-distance calibrations. These calibrations were subsequently checked in our laboratory and were found to be accurate However the calibration scale was rechecked for each echocardiographic measurement since some variation may occur with changes in gain settings and variation in calibration may also occur over the range of the screen The calibrations were measured during videotape motion replay to allow better visualization of the scale Calibration factors were determined and were applied to each volume calculation

significantly from corresponding values for Model 1 With Model 3 (Table I) the short axis diameter length method correlation coefficients were also excellent for both symmetric and asymmetric ventricles 0 984 and 0 956 respectively Mean percent errors were 26 6% and 35 4% respectively Only the correlation coefficient for symmetric ventricles was significantly lower for Model 3 than for Model 2 other values were not significantly different With Model 4 (Table I) the long axis area length method the correlation coefficient was excellent for symmetric ventricles 0 972 but was substantially lower for asymmetric ventricles 0 886 the latter value was also significantly lower than the corresponding value for Model 3 Mean percent errors were 30.9% for

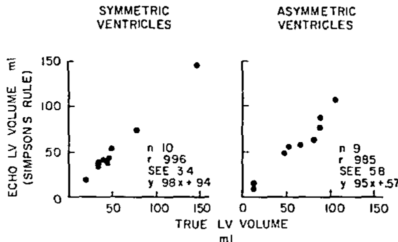

Fig 5 Comparison of volume in formalin fixed left ventricles, cross-sectional echocardiography (Simpson s rule Model 1) on the Y axis versus true volume on the X axis A linear regression analysis was performed for calculated versus true volume the regression equation is shown The correlation coefficients were excellent for both symmetric (n = 10) and asymmetric (n = 9) ventricles, 0 996 and 0 985 respectively N = number of ventricles r = correlation coefficient SEE = standard error of estimate

cles LV volume calculated by the above five models was compared to true fluid volume of the LV Linear regression analysis was performed and standard error of estimate was calculated Per cent error was determined as follows

$$\text{percent error} = \frac{\text{calculated LV volume} - \text{true LV volume} \times 100}{\text{true LV volume}}$$

For each of the five models calculated LV volume was plotted against true LV volume Percent errors were plotted and mean percent error was calculated as an average of absolute percent errors for the 10 symmetric and nine asymmetric left ventricles

Results

For 10 symmetric hearts the mean ratio of septal lateral diameter to anterior posterior di ameter was 1 23 ± 0 06 (mean ± SEM) and vol ume ranged from 19 5 to 146 milliliters For nine asymmetric hearts the mean ratio was 1 80 ± 0 07 and volume ranged from 13 0 to 105 5 milliliters

Results of both linear regression and percent error analyses are summarized in Table I for all five mathematic models Correlation coefficients and mean percent error are listed for a compari son between echo volume and true volume of the formalin fixed left ventricle The results of testing mathematic models 1 and 5 are graphically illus trated in Figs 5 and 6 Points are plotted for calculated volume versus fluid volume for 10 symmetric ventricles and for nine asymmetric ventricles the regression equation correlation coefficient standard error of estimate and mean percent error are listed for each model. With symmetric ventricles excellent correlations were obtained for all mathematic models correlation coefficients ranged from 0 996 to 0.967 and mean percent error ranged from 5 9% to 30 9% Although reductions in r value with asymmetric ventricles were statistically significant for all five models only in Models 4 and 5 did r values decline below 0 95

Fig 5 shows a comparison between echo vol ume by the Simpson s rule (Model 1) on the Y axis and true volume on the X axis The correla tion coefficients were excellent for both symmet ric and asymmetric ventricles 0 996 and 0 980 respectively Mean percent errors were low for both groups 5 9% to 9.8% respectively

With Model 2 (Table I) the short axis area length method correlation coefficients were excellent for both symmetric and asymmetric ventricles 0 993 and 0.974 respectively mean percent errors for Model 2 were low 10 1% and 20 3% respectively These values did not differ

lumen toward the base of the LV Since the internal cavity structure of the formalin fixed left ventricle was not precisely the same as that of the normal left ventricle the regression equation for each mathematic model may not be appropriate for application to the left ventricular volume in the beating heart Nevertheless the formalin fixed left ventricle is quite useful in evaluation of the relative merits of mathematic models for quantification of left ventricular volume For Model 1 in particular our results indicate that no regression equation is necessary in either symmetric or asymmetric ventricles this is evident from the fact that the regression slopes (m) are very close to 1 0 and regression intercepts (I) are very close to zero (Table I)

In summary this in vitro study of cross sectional echocardiography has demonstrated that volume of the symmetric left ventricle may be quantified reliably with all mathematical models tested but volume of the asymmetric left ventricle is quantified most reliably by models that incorporate left ventricular length and either short axis area or two short axis diameters

Summary

Cross sectional echocardiography was utilized for quantification of volume in 19 formalin fixed left ventricles in the presence or absence of ventricular symmetry, defined by the ratio of septal lateral to anterior posterior diameter In 10 symmetric ventricles this ratio was 1 23 ± 0 06 (mean ± SEM) whereas in nine asymmetric ventricles the ratio was 1 80 ± 0 07 Area diameter and length measurements were obtained from short and long axis cross sectional images of the left ventricle and volume was calculated by five mathematical models previously described To evaluate the reliability of each model echocardiographic left ventricular volume was compared by linear regression and percent error analyses to directly measured fluid volume

In symmetric ventricles excellent correlations (r = 0 996 to 0 967) and reasonable mean percent errors (6% to 31%) were observed for all models In asymmetric ventricles models utilizing short axis area or two short axis diameters retained high correlation coefficients (r = 0 985 to 0 9?6) and similar mean percent errors but standard formulas previously used with M mode echo and angiography showed lower correlations (r = 0.8?? to 0 873) and higher mean percent errors (?% to 54%) Thus, in the presence of ventricular asymmetry analysis of short axis areas or diameters with cross sectional echocardiography is well suited for quantification of left ventricular volumes

ymmetric ventricles and a substantially higher 32.1% for asymmetric ventricles

Fig 6 shows a comparison between echo volume by the cube method (Model 5) on the Y axis and the true volume on the X axis The correlation coefficient was very good for symmetric ventricles r = 0.967 in contrast the correlation coefficient was substantially lower for asymmetric ventricles r = 0 873 Mean percent error was substantially higher for asymmetric ventricles (53.5% versus 29 8%) than for symmetric ventricles

Discussion

This study of cross sectional echocardiography demonstrates that volume can be accurately quantified in asymmetric as well as symmetric left ventricles using either short axis areas (Models 1 and 2) or two short axis diameters (Model 3) and ventricular length Mathematical models of the present study were developed and tested in previous studies from this laboratory quantifying mass of the left ventricle in anesthetized dogs and volume in formalin fixed left ventricles [7, 8] Models 1 and 2 utilizing short axis area and length of the left ventricle were developed specifically for cross sectional echocardiography These models proved to be the most reliable for volume and mass quantification of the left ventricle [8] by virtue of the high correlation coefficients low mean percent errors and even distribution of regression points about the line of identity The fact that Model 2 proved statistically to be just as reliable as Model 1 in the present study as well as in the LV mass study[7] emphasizes the practical importance of the simple formula $V = 5/6\,AL$ in both experimental and clinical application Interestingly for asymmetric ventricles of the present study Model 3 ($V = \pi/6\, D_1 D_2 L$) proved statistically to be just as adequate as Model 2 for LV volume quantification

Model 4 the long axis area length method normally used with angiography and Model 5 the cube method used with M mode echocardiography were quite reliable for quantification of volume in symmetric ventricles but much less reliable in the presence of ventricular asymmetry These findings of the present study are in general agreement with the findings of previous clinical studies of left ventricular volumes In patients with symmetric myocardial wall motion [1-4] good correlations were demonstrated between M mode echocardiography and angiography but in patients with regional myocardial asynergy poor correlations were encountered [6] indicating that estimation of asymmetric volumes from a single M mode echo dimension is unreliable These observations reveal the major underlying assumption of Models 4 and 5 namely that the endocardial surface must be sufficiently symmetrical to be described as an ellipsoid Because the manifestation of ventricular asymmetry due to myocardial ischemia or infarction is usually apparent only during the systolic phase of the cardiac cycle the major error in volume quantification occurs during systole

Clinical application of these cross sectional echocardiographic mathematic models is dependent on the quality of short axis cross sectional images available in the human If endocardial definition is adequate Models 1 2 or 3 may account for the presence of ventricular asymmetry in the computation of left ventricular volume Since it is difficult in patients to obtain adequate short axis images at more than one or two levels of the left ventricle Models 2 and 3 will probably be most applicable in the clinical situation The ventricular asymmetry simulated in this study was a minor axis asymmetry generally consistent for the entire length of the left ventricle thus Models 2 and 3 utilizing measurements from only one minor axis section gave results only slightly less reliable than Model 1 Since dyssynergy due to regional myocardial ischemia or aneurysm may not extend the entire length of the left ventricle but may instead be localized (for instance to the apical half of the ventricle) Models 2 and 3 might tend to be less reliable than Model 1 unless the volume computations incorporate measurements from a minor axis section within the dyssynergic region Thus the particular type of ventricular asymmetry used in this study may not have a specific clinical or physiologic analogy but the results of this study may nevertheless have general implications for volume quantification in the presence of ischemia infarction aneurysm or asymmetric hypertrophy

The effects of formalin fixation procedures in the present study were reflected in minor changes of ventricular chamber characteristics (1) some loss of prominence of papillary muscle projections into the ventricular cavity (2) a smoothing effect on rough edges of the endocardial surface (trabeculae carneae) and (3) a constriction of the cavity

The method of the measurement of VMRT was described in detail previously [1] In brief a series of rectangular pulses (100 Hz 1 msec in duration) were given throughout the ventricular vulnerable period with the electrode attached to a potential ly nonischemic area of the left ventricle The intensity of pulses was increased gradually until more than five extrasystoles occurred successive ly to obtain VMRT In order to measure mito chondrial function it is necessary to avoid the myocardial injury induced by any artifact such as regional burn by DC countershock In many cases less than 10 successive ventricular extr isys toles did not lead to ventricular fibrillation and when the electrical stimulus was stopped cardiac rhythm returned to normal without DC counter shock Therefore we use VMRT instead of ven tricular fibrillation threshold (VFT) as an index of arrhythmogenicity Although VMRT was less than VFT good reproducibilit of this method was observed

Venous blood was taken from the femoral vein and blood pH serum elc tr lytes Na K Ca

Canine hearts of another half of each gro were isolated immediately after 15 or 30-minute occlusion and myocardial mitochondria were prepared according to Hatefi s method In order to measure the respiratory control index (RCI and ADP/O of the myocardial mitochondria 2 ml of mannitol reaction mixture (0 3 M man tol 10 mM phosphate 2 5 mM MgCl 10 mM KCl and 0 25 mM EDTA pH 7 4) and 0 3 ml of the mitochondrial sample (10 mg mitochondrial protein per milliliter) were added together with 0 1 ml of potassium succinate (0 2 M) a d 0 ml or 0 03 ml of ADP (0 01 M) as substrates to reaction cell mounted with the oxygen electrode (Kyusui Kagaku Ltd)

ATP production rate (nmoles/mg mitoch drial protein/minute) was calculated as ADP O × oxygen consumption rate in State III mitochondrial protein/minute

Results

In Fig 2 the time courses in VMRT in the 15 minute occlusion groups are shown In the saline infused group the initial mean val e of 1 59 ± 0 09 mA (mean ± SE) was significan decreased to 1 13 ± 0 08 mA 1 07 ± 0 08 mA at 7 5 and 15 minutes after ligation respectively Reduced VMRT 1 18 ± 0 07 mA was observed at 10 minutes after the release of ligation howev er at 20 minutes after the release VMRT

Recovery time course of ventricular vulnerability after coronary reperfusion in relation to mitochondrial function in ischemic myocardium

Satoru Sugiyama, M.D.*
Takayuki Ozawa, M.D.*
Tadayuki Kato, M.D.**
Shohachi Suzuki, M.D.*
Nagoya, Japan

Although in 1935 Tennant and Wiggers noted a high incidence of ventricular arrhythmias (reperfusion arrhythmias) after the sudden restoration of blood flow to an occluded coronary artery in canine experiments, and similar findings have been observed by other investigators, reperfusion arrhythmias remain less familiar than the arrhythmias seen during acute coronary occlusion. However, with the advent of coronary bypass surgery and with advances in coronary angiography indicating the relationship between coronary artery spasm and Prinzmetal's angina, the subjects of ventricular arrhythmias and ventricular vulnerability to fibrillation following the release of a previously ligated coronary artery have attracted much interest and have been extensively studied in recent years. Nevertheless, the mechanism whereby ventricular fibrillation is precipitated during reperfusion of ischemic myocardium remains uncertain.

We have studied the time courses in ventricular multiple response threshold (VMRT) during coronary occlusion and after release of occlusion and have suggested that the recovery time course in VMRT closely relates to recovery of heart mitochondrial function following coronary reperfusion.

In this study, the effects of the duration of occlusion time and infusion of fatty acid emulsion or infusion of coenzyme Q on myocardial mitochondrial function were investigated in relation to the recovery time courses in VMRT following coronary reperfusion.

Methods

Forty-eight mongrel dogs of both sexes and weighing between 10 and 15 kg were anesthetized with sodium pentobarbital (30 mg/kg) intraperitoneally. Under artificial respiration, the chest was opened in the fourth or fifth intercostal space and the heart was suspended in a pericardial cradle. A silk ligature was placed at the proximal branch of the left anterior descending coronary artery.

The dogs were divided into four groups (12 dogs each) according to the duration of coronary occlusion time and infusion of drugs.

Group 1. 15 minute occlusion after saline infusion.

Group 2. 15 minute occlusion after free fatty acid emulsion (contents are shown in Table I) ml/kg infusion.

Group 3. 30 minute occlusion after saline infusion.

Group 4. 30 minute occlusion after coenzyme Q 5 mg/kg infusion.

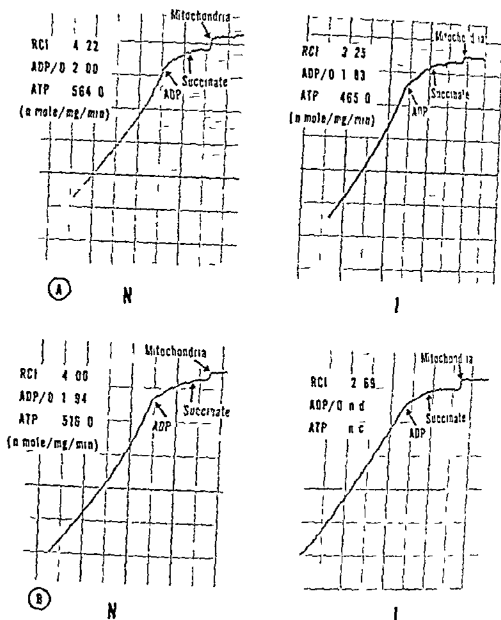

Fig 3 A and B Representative traces of mitochondrial respiration in the saline + 15 minute occlusion group (A) and in the fatty acids + 15 minute occlusion group (B) Infusion of fatty acids accelerated dysfunction of the mitochondria in the ischemic area

The reduced value at 30 minutes was lowered significantly less than that in the saline infused group At 10 and 20 minutes after reperfusion reduced VMRT 1 20 ± 0 07 mA and 1 38 ± 0 05 mA was observed respectively However decrease in VMRT was less remarkable than that of the saline infused group VMRT at 30 minutes after the release of ligation recovered to a value which is not significantly different from the preligation value

These results showed us that it took 40 minutes after reperfusion in the saline infused group and 30 minutes in the coenz me Q infused group to recover the value of VMRT to that before ligation respectively

Concerning the heart rate blood pH and serum levels of Na K Ca Cl no significant changes were detected between the two groups

Table III represents mitochondrial indices of 30 minute occlusion groups As shown in the Table mitochondria isolated from an ischemic area showed significantly lowered indices compared with those of nonischemic mitochondria By 30 minute occlusion ischemic mitochondria of the saline infused group showed further lowered [illegible] those of the

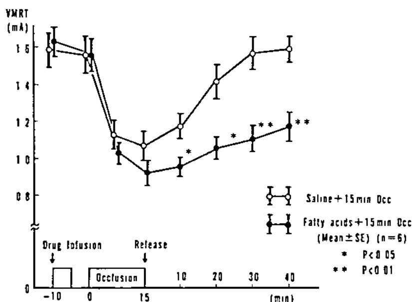

Fig 2 Time courses in VMRT of the 15-minute occlusion group In the fatty acid infused group the recovery time course of VMRT was significantly retarded

returned to a value which is not significantly different from that before ligation

In the fatty acids-infused group the initial value of 1 63 ± 0 08 mA was not significantly decreased by fatty acid infusion itself After ligation VMRT decreased significantly to 1 03 ± 0 06 mA at 7.5 minutes after ligation and to 0 92 ± 0 07 mA at 15 minutes after ligation The reduced VMRT persisted i e 0 96 ± 0 05 mA 1 06 ± 0 06 mA 1 11 ± 0 07 mA and 1 18 ± 0 08 mA at 10 20 30 and 40 minutes after the release of ligation respectively These reduced values were significantly lower than those of the saline infused group

These results showed us that it took 20 minutes in the saline infused group and over 40 minutes in the fatty acid-infused group respectively to restore the value of VMRT to that before ligation

Concerning the heart rate blood pH and serum levels of Na K Ca Cl no significant changes were detected in the two groups

Indices of mitochondrial function (RCI ADP/O ATP production rate) are shown in Table II In both groups mitochondria isolated from an ischemic area showed significantly lowered RCI comparing with that of mitochondria isolated from a nonischemic area It was noted that mitochondria isolated from an ischemic area of the fatty acid-infused group showed significantly lowered indices compared with those of ischemic mitochondria of the saline infused group Ischemic mitochondria of the fatty acid-infused group showed no reestablishment of the controlled respiration after the addition of ADP (Fig 3) i e by ischemia and more by fatty acid infusion myocardial mitochondria became loosely coupled showing little or no dependence of respiratory rate on ADP Thus ADP/O and ATP production rate could not be calculated

In Fig 4 the time courses in VMRT in the two 30 minute occlusion groups are shown In the saline infused group the initial value of VMRT 1 56 ± 0 09 mA was decreased to 1 20 ± 0 07 mA 1 06 ± 0 06 mA and 0 99 ± 0 05 mA at 10 20 and 30 minutes after the ligation respectively Reduced VMRT 1 02 ± 0 07 mA 1 10 ± 0 08 mA and 1 23 ± 0 08 mA was observed at 10 20 and 30 minutes after the release of ligation respectively while VMRT measured at 40 minutes after the release of ligation recovered to a value which is not significantly different from the preligation value In the group infused with coenzyme Q (5 mg/kg) the initial value of 1 62 ± 0 07 mA was decreased to 1 21 ± 0 05 mA 1 24 ± 0 05 mA and 1 21 ± 0 05 mA at 10 20 and 30 minutes after ligation respectively

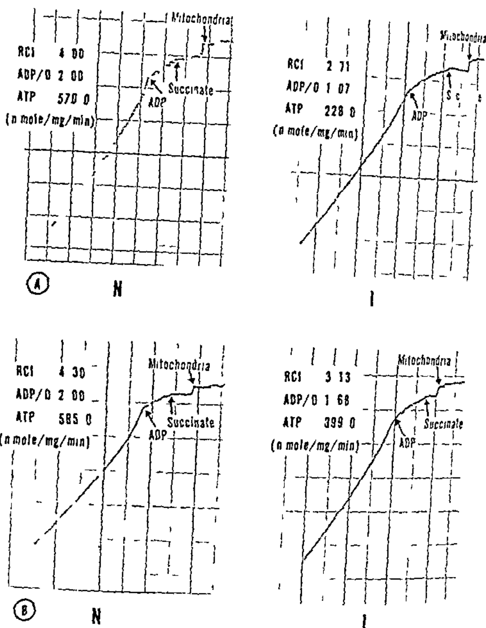

Fig 5 A and B Representative traces of mitochondrial respiration in the saline + 30 minute occlusion group *(A)* and in the coenzyme Q + 30 minute occlusion group *(B)* Coenzyme Q infusion prevented mitochondrial dysfunction induced by 30 minutes of ischemia

chondrial membrane and the mitochondria to be loosely coupled Coenzyme Q, isolated first by Crane and colleagues is an important factor of the mitochondrial electron transfer system as shown in Fig 7 Coenzyme Q transfers electrons from Complex I or II to Complex III In the mitochondria obtained from the ischemic area the electron transfer activity between Complex I and III was reduced and the mitochondrial dysfunction induced by ischemia might be derived partly from this electron transfer disturbance Administration of coenzyme Q preserved even if not completely the activity of the electron transfer system and resulted in better mitochondrial function compared with controls (Table III)

It is interesting that the recovery time course of VMRT of the saline + 15 minute occlusion group was similar to that of the coenzyme Q + 30 minute occlusion group The recovery time course in VMRT of the fatty acid emulsion + 15 minute occlusion group was also similar to that of the saline + 30 minute occlusion group These relationships of the two groups were also apparent in mitochondrial damage In other words, the

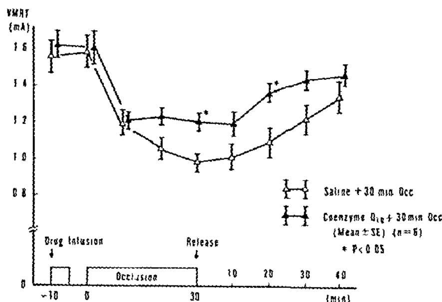

Fig. 4. Time courses in VMRT of the 30-minute occlusion group. In the coenzyme Q-infused group recovery of VMRT was significantly shortened compared to that of the saline infused group.

minute occlusion group (Tables II and III). However these indices were significantly preserved by the administration of coenzyme Q.

Fig. 5 shows representative traces of mitochondrial respiration in these two groups. It was also confirmed that the administration of coenzyme Q prevented mitochondrial dysfunction caused by ischemia.

Discussion

We have reported[13] that VMRT which was lowered during coronary occlusion recovered in the course of time after the release of ligation and that the recovery time course in VMRT depended upon the duration of the preceding occlusion time. But it remains obscure which factor truly affects the recovery time course in VMRT.

Our previous report showed that the administration of fatty acid emulsion of 1 ml/kg did not cause mitochondrial dysfunction in the well oxygenated heart but accelerated the mitochondrial dysfunction induced by ischemia. The report also showed that the infusion of fatty acids delayed the recovery of VMRT. According to these results we have suggested that mitochondrial function is one of the important determining factors of the recovery time course in VMRT.

As summarized in Fig. 6 and Table IV this experiment revealed that (1) the longer the duration of occlusion time the longer was the necessary recovery time in VMRT, (2) the longer the duration of occlusion time the more severe was the mitochondrial damage caused, (3) fatty acid infusion accelerated mitochondrial damage induced by ischemia and coenzyme Q_{10} administration prevented the mitochondrial damage, and (4) the recovery time in VMRT was in parallel with mitochondrial damage. As for mitochondrial function, myocardial ischemia suppressed the activity of the mitochondrial electron transfer system and β oxidation cycle of fatty acids because of the accumulation of acyl CoA which inhibits the ADP ATP exchange reaction of mito

severe the mitochondrial damage the longer was the necessary recovery time in VMRT.

Any proposals as to possible mechanisms for the observed results must be highly speculative. However if the depletion of cytosolic ATP which is produced mainly by mitochondria shortened the action potential duration as Cowan and Vaughan Williams reported the shortened duration of the action potential could be responsible for reentry in ventricular muscle and ventricular fibrillation. Therefore it is possible that mitochondrial function i.e. the rate of ATP supply is one of the important determining factors in the recovery time courses in VMRT.

Summary

This experiment was designed to investigate the effect of the duration of occlusion time and the infusion of fatty acid emulsion or that of coenzyme Q on myocardial mitochondrial function and on the recovery time course in VMRT following coronary reperfusion. Forty eight anesthetized mongrel dogs were divided into four groups based on the duration of the occlusion time and the infused drug. Group 1 was the saline + 15 minute occlusion group. Group 2 was the fatty acid emulsion (1 ml/kg) + 15 minute occlusion group. Group 3 was the saline + 30 minute occlusion group and Group 4 was the coenzyme Q (5 mg/kg) + 30 minute occlusion group. After the drug administration (saline, fatty acid emulsion or coenzyme Q) the left anterior descending coronary artery was ligated for 15 or 30 minutes. In one half of each group canine hearts were isolated immediately at 15 or 30 minutes after ligation to prepare myoc[illegible] mitochondria. In the other half of each gr[illegible] the ligation was released and coronary flow w[illegible] reperfused. VMRT was measured before d[illegible] and after the ligation. The recovery time course [illegible] the saline + 15 minute occlusion group was simi[illegible] lar to that of the coenzyme Q_{10} + 30-minute occlusion group and the recovery time co[illegible] the fatty acid + 15 minute occlusion group was similar to that of the saline + 30 minute occlu[illegible] sion group. This relationship of the two group[illegible] was recognized in the mitochondrial dama[illegible] suggested that mitochondrial damage in oth[illegible] words energy supply dysfunction is one of the determining factors of recovery in VMRT af[illegible] coronary reperfusion.

An electrocardiographic—pathologic correlative study on left axis deviation in hypertensive hearts

Tatsuji Takagi M D *
Ryozo Okada, M D **
Tokyo Japan

Left axis deviation (LAD) has been generally ascribed to left anterior hemiblock (LAH)[1] or left anterior focal block [4] While some investigators have attempted to find a correlation between LAD and LAH questions such as whether LAD is in fact consistent with LAH whether LAH is specific for LAD and what degree of LAD indicates LAH remain to be answered Therefore we carried out a study to correlate LAD and conduction system pathology in autopsied hypertensive hearts with special reference to the left bundle branch (LBB)

Materials and methods

The well preserved hearts of 35 arterial hypertension patients (18 males 17 females, ranging in age from 38 to 89 years) autopsied between 1970 and 1976 were studied and compared pathologically Only specimens from essential (EH) and renal hypertension (RH) cases and cases with hypertension complicating aortic insufficiency (AI) are included in this study The patients whose electrocardiograms (ECGs) showed left bundle branch block (LBBB) or myocardial infarction were excluded

The materials were divided into three groups based on mean QRS axis calculated by the triaxial reference system in the frontal plane Group 1 consisted of seven EH, three RH, and two AI cases with left axis deviation of −89 degrees to −30 degrees In Group 2 there were eight EH two RH and one AI with semi left axis deviation of −29 degrees to 0 degrees Group 3 was comprised of six EH, five RH and one AI with normal axis deviation of 1 degree to 89 degrees

After gross examination of the hearts, left ventricular volume was calculated according to the method of Lev and associates [5]

For histological examination of the atrioventricular conduction system step sections were prepared according to a modification of the method of Lev and co-workers In addition to the regular four blocks, three further blocks were obtained—i e , one block each of the peripheral portions of the left anterior and posterior radiation (LBB and LBB, respectively) and one block from the apex including the left and right ventricle and interventricular septum From each block five 7 micron thick slices were cut stained with hematoxylin eosin (HE) periodic acid Schiff (PAS), and Elastica van Gieson (EvG) method and observed under a light microscope If necessary additional histologic sections were used

Results

The ages and sex distribution of the patients QRS axes cardiac weights, and left ventricular measurements are shown in Table I Except for the QRS axes there were no significant differences among the three groups Incidence of LVH by ECG using criteria of Sokolow and Lyon was 58% in Group 1 73% in Group 2 and 83% in Group 3

To compare severity of the lesions in the conduction system four categories ranging from absent to severe were established (Table II) L

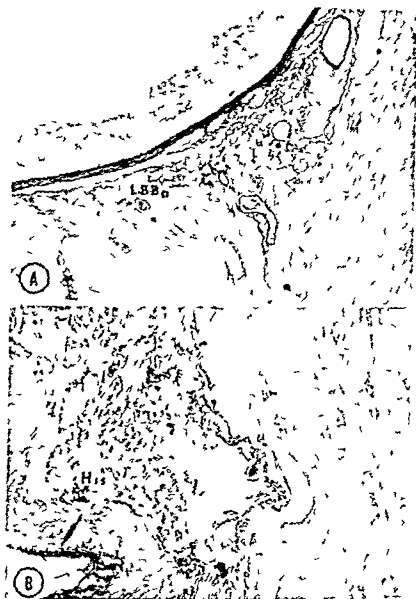

Fig 1 *A* A 40-year old male with fibrosis and fatty degeneration of the peripheral portion of the LBB (Elastica Van Gieson stain original magnification ×40) *B* An 85 year old male with fibrosis of the His bundle (His) (Elastica Van Gieson stain original magnification ×40) Both specimens are from Group 1

cells were intact at LBB_p (Fig 4C) These findings were consistent with LAD

Case 3 A 58 year old male presented with aortic insufficiency and hypertension He died of congestive heart failure The ECG initially revealed the QRS axis to be −9 degrees (Fig 5*A*) at a later time the axis was noted to have shifted to the left and finally the axis was −30 degrees with junctional rhythm and slight widening of the QRS (Fig 5*B*) Histology revealed marked reduction of the conduction cells at LBB and LBB_p due to entrapment by thickened subendocardial fibrous tissue (Fig 5C D E and F)

Case 4 A 43 year old female presented with chronic renal failure (RH) While the QRS axis was normal at 43 degrees (Fig 6A) both anterior and posterior radiations of the LBB were damaged by marked fibrosis and fatty infiltration (Fig 6*B* and *C*)

Discussion

1 Extent of LAD in LAH To our knowledge no genuine studies on the correlation between the electrocardiographic and pathologic findings have been published and there is no consensus regarding the extent of LAD which is compatible with LAH

Demoulin and Kulbertus reported a correla-

Table I Comparison of the three groups based on QRS axis and gross pathological findings

Group	No of cases	Sex		Age (years)	Electrical axis (°)	Cardiac weight (g)	Left ventricle	
		M	F				Thickness (mm)	Volume (mL)

2	11	6	5	69.3 ± 4.[illegible]	−16.4 ± 6.2	399 ± [illegible]6	14.4 ± 2.1	14.2 ± 6.5
3	12	6	6	6[illegible].0 ± 14.9	46.3 ± 18.6	447 ± 11[illegible]	14.1 ± 1.9	19.6 ± 12.[illegible]

(Mean ± standard deviation)

Table II Severity of the lesions in the conduction system

Group	His bundle				LBB				LBB			
	0	+	++	+++	0	+	++	+++	0	+	++	+++
1	6	4	0	2	2	5	4	1	0	2	1	9
2	5	2	4	0	2	6	1	2	3	4	2	2
3	7	4	1	0	4	4	1	3	1	6	2	3

LBB = left bundle branch (p posterior, a anterior)
Degree of severity 0 normal + mild ++ moderate +++ severe (Severe lesion means reduction of the conduction cells more than 50%)

Table III Histological findings of the conduction system and incidence of severe lesions

Group	His bundle			Posterior radiation (LBB_p)			Anterior radiation (LBB_a)			
	Fibrosis	Calcification	Total	Fibrosis	Degeneration	Total	Fibrosis	Degeneration	Bleeding	Total
1	1	1	2	1	0	1	5	2	2	9
2	0	0	0	1	1	2	1	1	0	2
3	0	0	0	2	1	3	2	1	0	3

This table severe lesion means reduction of conduction cells by more than 50% One of our group Okada[7] based upon his numerous electrocardiographic pathologic correlation studies recognized as empirical evidence that 50% reduction of conduction cells almost always shows some kind of conduction disturbance Therefore we may call severe lesions with over 50% reduction of conduction cells at LBB anatomical LAH

In Group 1 nine of 12 (75%) specimens showed severe lesions at LBB one of these had lesions at both LBB and LBB_p and another one showed severe lesions at the peripheral portion (Fig 1A) There were also two cases with severe lesions at the bifurcation of the His bundle (Fig 1B) the ECG showed right bundle branch block (RBBB) In this group there was one case without severe lesions in the conduction system the electrical axis was −36 degrees In Group 2 there were two cases each with severe lesions at both radiations and in Group 3 there were three similar cases

The incidence and site of severe lesions is shown in Table III In the 35 specimens fibrosis (Fig 2A) at the His bundle LBB or LBB_p was noted in 13 (37%) degeneration was found (Fig 2B) in six (17%) bleeding (Fig 2C) was seen in two (6%) and calcification (Fig 2D) was noted in one (3%) As for the relationship between the type of hypertension and severe lesions fibrosis was noted most frequently in EH (38%) and degeneration in RH (60%)

Case reports

Case 1 An 89 year old female presented with polycystic kidney (RH) and a QRS axis of −45 degrees (Fig 3A) Histology revealed the subendocardial connective tissue to be thickened and to interrupt the conduction cells of LBB almost completely (Fig 3B and C) At the LBB_p there was mild fibrosis at the proximal portion and the conduction cells were hypertrophic

Case 2 A 77 year old female presented with subarachnoid hemorrhage (EH) and a QRS axis of −58 degrees (Fig 4A) Histology revealed massive bleeding at LBB (Fig 4B) and slight bleeding under the subendocardium The conduction

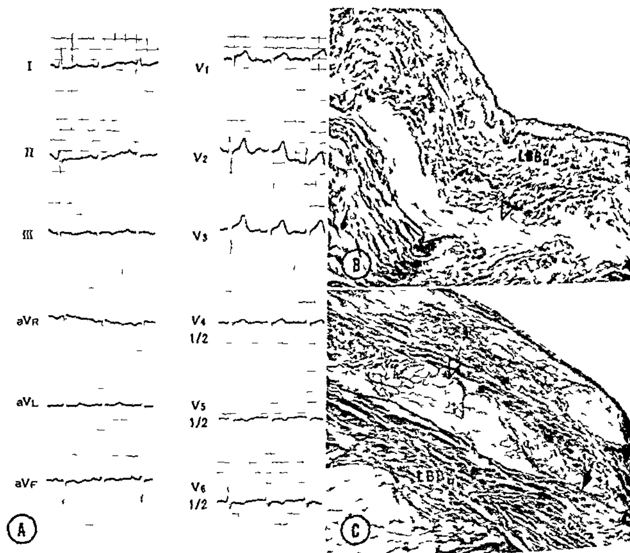

Fig 3 Case I A Electrocardiogram B Proximal portion of the LBB C Somewhat distal portion of the LBB Thick fibrosis *(solid arrows)* interrupts the conduction cells *(open arrows)* (Elastica Van Gieson stain original magnification ×40)

and LAH Although we used the step sectioning (semi serial) method rather than the serial sectioning method our study fulfils the proposed criteria for a genuine correlative study

2 LAD in LAH Conduction delay at LBB is thought to effect LAD in LAH[1 1 1 13] Focal lesions at the His bundle which effect longitudinal dissociation [1] produce LAD and RBBB[16 17] In our series there were two such cases Since the bifurcation of the His bundle can be considered to represent the proximal portion of LBB a block of that portion can be regarded as modified LAH and LAD in LAH can be ascribed to conduction delay at LBB

3 A concept of cancellation In the present series, there were one Group 1 two Group 2 and three Group 3 cases with severe lesions at LBB and LBB_p To answer the questions as to why the spectrum of the mean QRS axis in the frontal plane was so wide despite similar changes at both radiations and why complete LBBB did not occur we propose two hypotheses First conduction disturbances are not always either severe or complete rather in some cases a conduction delay occurs Our second hypothesis is that axis deviation is produced by differences in conduction velocity between the two divisions From these points of view the distribution of the QRS axis summarized as shown in Table IV Only complete conduction block of both divisions yields LBBB and LAD occurs in cases of complete conduction block of LBB or slower conduction at the LB

Fig 2 Histologic findings in severe lesions *A* A 1 year old male from Group 1 with fibrosis at LBB *(solid arrow)* (Elastica Van Gieson stain original magnification ×40) *B* A 38-year-old male from Group 3 with vacuolization and edema at LBB *(solid arrow)* (Elastica Van Gieson stain original magnification ×40) *C* A 60-year old female from Group 1 with bleeding at LBB (Hematoxylin and eosin stain original magnification ×40) *D* An 85 year old male from Group 1 with calcification *(solid arrow)* of the central fibrous body at the His bundle (Elastica Van Gieson stain original magnification ×40) *Open arrows* indicate conduction cells in *A* *B* and *D*

tive study on the conduction system and LAD They found that nine of 10 cases had severe LBB lesions and five of these showed predominant lesions at the anterior subdivision However as their series included some myocardial infarction cases we do not consider theirs a genuine correlative study linking ECG pattern and the conduction system For the same reason we have our reservations about the study reported by Entman and associates

There are two well known criteria in ECG for LAH One is LAD in excess of −45 degrees as postulated by Rosenbaum and co workers and another is LAD in excess of −30 degrees as set down by Kulbertus and colleagues and by Gopal[11] In our series defining severe lesion over 50% reduction of conduction cells at LBB as anatomical LAH and by using the former criteri on sensitivity (true positives/true positives + false negatives) was 25% (four out of 16) and specificity (true negatives/true negatives + false positives) was 100% (19 out of 19) and using the latter criterion sensitivity 69% (11 out of 16) and specificity 95% (18 out of 19) While in the criterion of Rosenbaum and associates specificity was high but sensitivity low we think that the criterion of Kulbertus and associates[10] and of Gopal is more appropriate

We propose that serial sections control materials and relatively uniform specimens from patients without other heart disease such as myocardial infarction or congenital heart disease which may affect the QRS axis should be the criteria for a genuine correlative study on LAD

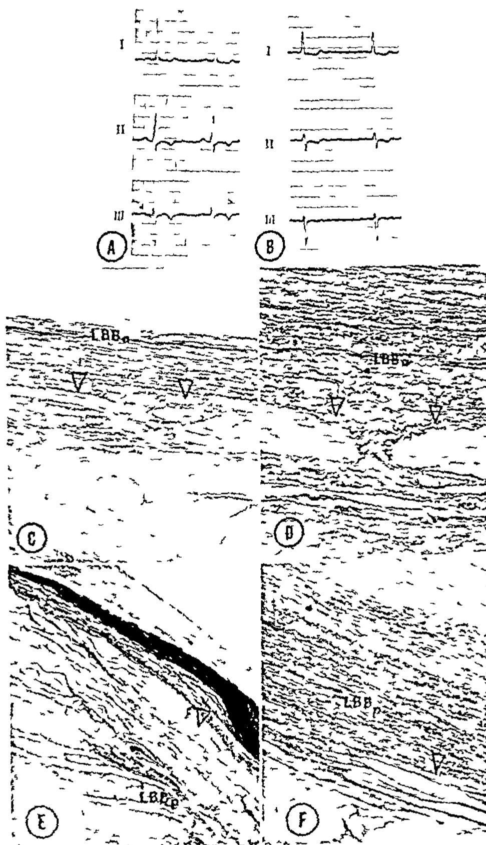

Fig 5 Case 3 *A* Electrocardiogram on Oct 25 1972 *B* Electrocardiogram on July 10 1973 *C* Histologic section shows reduction of conduction cell (Elastica Van Gieson stain original magnification ×40) *D* Thick fibrosis at the LBB (Elastica Van Gieson stain original magnification ×100) *E* Proximal portion of LBB, showing preserved conduction cell (Elastica Van Gieson stain original magnification ×40) *F* Thick fibrosis interrupt the conduction cell of LBB at the distal portion of *E* (Elastica Van Gieson stain original magnification ×40) *Open arrows* indicate conduction cells in *C* to *F*

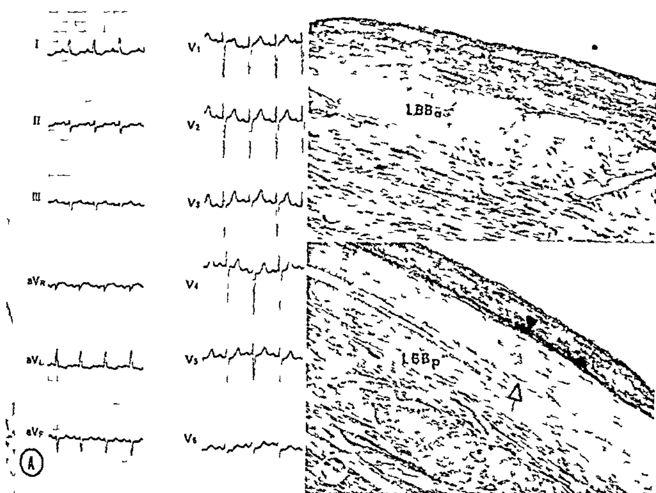

Fig 4 Case 2 *A* Electrocardiogram *B* Massive bleedin at the LBB (Hematoxylin and eosin stain original magnification ×40) *C* Slight bleeding *(solid arrow)* under the subendocardium Conduction cells *(open arrow)* are intact at LBB_p (Elastica Van Gieson stain original magnification ×40)

han at LBB_p In the same conduction delay of oth divisions each cancels the axis deviation of he other (cancellation) In cancellation LBBB loes not occur because of preservation of conduc ion in the LBB although it is slow and the QRS axis remains in the normal range In such cases slight prolongation of the QRS axis may occur

We may explain from our hypotheses that in one of the Group I cases LAD occurred because conduction disturbance was not complete and onduction velocity at LBB was slower than at LBB although severe lesions were present at oth divisions Furthermore five cases of Groups 2 and 3 in which the conduction delay in both divisions was almost the same did not show LAD possibly because of cancellation between LBB and LBB_p While there is no consensus as yet regarding the concept of cancellation it represents an important hypothesis which is based on our control study and it should be pursued further

4 **The two versus three division theory in LBB** Our hypothesis regarding the LBB divisions is based on the consideration that there are two main portions consisting of the anterior and posterior radiation Demoulin and Kulbertus[4] and Massing and James[5] stated that the septal division is between the two main radiations However histologically the septal division appears to be a part of the posterior radiation with cellular communications between it and the posterior radiation Based on this consideration

Table IV Relationship between QRS axes and mode of conduction in LBB

Radiation		LBB_a			
	Mode of conduction	Normal	Slow	Slower	Block
LBB	Normal	NAD	PAD	RAD	RAD
	Slow	LAD	C	RAD	RAD
	Slower	LAD	LAD	C	RAD
	Block	LAD	LAD	LAD	LBBB

Normal normal conduction Slow slow conduction velocity Slower slower conduction velocity Block complete conduction disturbance C cancellation NAD nonaxis deviation RAD right axis deviation

LAD and RAD partly include QRS axes with tendency of LAD and PAD respectively

investigated portions more peripherally located than the blocks of Lev and colleagues method, our materials were comprised of relatively uniform hypertension cases, and we included control materials Therefore we consider our results to be reliable for evaluating the pathology of the conduction system in hypertensive hearts

Summary

We performed an electrocardiographic pathologic correlative study using the step sectioning method in 35 autopsy specimens from patients with hypertension

Eleven out of 12 cases (91 7%) in Group 1 had severe lesions at LBB or the His bundle and we propose that LAD in excess of −30 degrees is a good criterion in hypertension for LAH

There were six cases in all with severe lesions at both radiations of the LBB In one case of Group 1 LAD is suggested to be due to slower conduction at the LBB than at the LBB_p and findings in five cases of Groups 2 and 3 led us to speculate that there was no LAD because of cancellation between the LBB and the LBB_p

Histopathology revealed fibrosis degeneration, bleeding and calcification which pathogenetically may derive from mechanical strain effected by hypertension and metabolic changes in cases with chronic renal failure

we evaluated our data according to the two division theory

5 Conduction system morphology Regarding the cause of conduction disturbances Lev pro posed sclerosis of the left side of the cardiac skeleton and Sugiura and co workers suggested mechanical stain because they found that muco polysaccharides were increased in the fibrotic area In hypertension mechanical strain strongly affects the interventricular septum leading to hypertrophy of the septal wall which may lead to conduction disturbances due to compression of the conduction system

All materials in the present series were from patients with hypertension and seven of 12 (58%) of Group I specimens revealed fibrotic changes in the conduction system indicative of accumulated mechanical strain Degenerative changes were present in 60% of RH cases suggesting that metabolic changes due to chronic renal failure produced edema and fatty infiltration in the conduction system The massive bleeding into LBB which produced LAD in two of our present cases appears to have been due to rupture of weakened small vessels induced by mechanical strain in the septal wall The presence of a focal increase in catecholamines or other vasoactive substances is probable in these cases

6 Step sectioning method While we used the step (semi serial) sectioning method rather than the more precise serial sectioning method patho logical changes occur in relatively narrowly cir cumscribed areas of the conduction system and our sections included these Moreover we also

electrodes was introduced through the sheath and under fluoroscopic control was advanced into the right ventricle After satisfactory positioning the outer sheath was either left in place in the femoral vein or was withdrawn and secured All patients remained at bed rest while the pacing electrode was in place

Fibrinogen scan One hundred microcuries of [1] I labelled fibinogen was injected intravenously and a scan was performed in both lower extremities prior to the electrode insertion[9], the scan was then repeated daily The test was considered positive when the radioisotope counts on two consecutive days were more than 20% of the baseline precordial measurements [15] In addition a disparity in counts of more than 20% between two areas on the legs was considered positive The test was interpreted as negative when the counts were unchanged Counts that were between 10% and 20% of control and counts that were elevated for less than 24 hours were considered equivocal

Assay of fibrin degradation products Blood for the preparation of serum was collected into thrombin and epsilon amino caproic acid The staphylococcal clumping test method was used [1] employing bacterial preparations sensitive to 0 75 μg/ml of fibrinogen A concentration of less than 8 μg/ml was considered normal [1]

Impedance plethysmography All studies were performed by the same trained technician using the cuff occlusive technique and a cuff occlusion time of sufficient duration to obtain optimal filling [1] The maximum rise on the plethysmographic recording during cuff inflation and the fall in three seconds following cuff deflation were determined From these findings a numerical figure representing the venous function index was derived On the basis of the venous function index score the results were interpreted as positive negative or equivocal

Venography Venography on the affected leg was performed in four patients with equivocal findings in the noninvasive tests In the remaining patients in this category venography could not be performed because of the unwillingness of the patient or his physician The studies were evaluated by two independent radiologists

Results

The patient population consisted of 12 men and eight women The average age was 71 years (range 33 to 86 years) In 18 patients the right femoral vein was used in two patients the left femoral vein was used

Incidence Of the 20 patients evaluated, five patients (25%) fulfilled the criteria for deep vein thrombosis (Table I) One had positive findings in all of the noninvasive tests There were 1[illegible] patients with equivocal abnormalities in the noninvasive tests Four of these underwent venography and all four had positive venograms. Of these one had thrombosis of the femoral vein one had thrombosis in several calf veins and one had thrombosis in both the thigh and calf veins the fourth patient had thrombosis of the entire deep venous system of the extremity This patient was the only one who had clinical evidence of deep vein thrombosis

Tests performed on the contralateral extremity were consistently negative except in one patient in whom the fibrinogen scan was positive and another in whom the impedance plethysmography was positive Neither of these patients had evidence of deep venous thrombosis in their catheterized leg

Clinical background The clinical background of the patients is shown in Table I Patients with deep vein thrombosis did not differ from those without thrombosis with regard to recent myocardial infarction type of heart disease or history of congestive heart failure

Technical aspects related to the pacing procedure The number of venepunctures used for the introduction of the electrode varied from one to 10 but in 15 cases fewer than three punctures were necessary A new electrode was used in the cases and the introducer sheath was pulled out in 16 cases The length of time that the pacing catheter remained in place varied from one to 1[illegible] days with an average period of 3 4 days

There was no relationship between the occurrence of deep vein thrombosis and the number of venepunctures the presence of the outer sheath in the femoral vein or the duration of electrode use None of the patients in whom an old electrode was used developed thrombosis

Clinical sequelae None of the patients showed evidence of local or systemic infection There were no clinical features suggestive of pulmonary embolism in any of the patients

Discussion

The transfemoral approach provides a reliable simple and rapid technique for temporary pacing

Transfemoral temporary pacing and deep vein thrombosis

Boston Mass

Transfemoral placement of a pacing catheter is a widely employed approach for temporary pacing[1,3] Few complications of this technique have been reported among which deep vein thrombosis has been only rarely mentioned [6] The clinical diagnosis of deep vein thrombosis has been shown to be unreliable [8] The development of reliable noninvasive tests[9,1] has provided the opportunity to evaluate the incidence of deep vein thrombosis associated with transfemoral pacing The diagnosis of deep vein thrombosis was based on I fibrinogen scanning impedance plethysmography and measurement of fibrin degradation products in all patients In four patients venography was also performed

Materials and methods

Patients who would require a temporary pacemaker for a minimum of 24 hours were studied Patients who were critically ill who were on anticoagulant therapy or who had a history of previous venous disease thromboembolic disease or hemoglobinopathies were excluded from the study During the period May 1978 to March 1979 20 patients were studied after obtaining informed consent Prior to the insertion of the pacemaker electrode I fibrinogen was injected impedance plethysmography was performed on both extremities and blood was drawn for fibrin degradation products Following pacer insertion the fibrinogen scan and assay of fibrin degradation products were obtained daily and impedance plethysmography was performed on alternate days Two observers made daily recordings of the presence or absence of leg pain edema tenderness change in leg and thigh circumference and Homans sign A study was terminated three days following the removal of the electrode unless the tests were positive at that time in which case they were continued until the tests returned to normal Whenever possible venography was performed in patients with equivocal results in the noninvasive tests Clinical information regarding the patients was not provided to the investigators analyzing the diagnostic tests

Based on the findings of clinical observation fibrinogen scan assay of fibrin degradation products impedance plethysmography and venography the following criteria were used to establish the diagnosis of deep vein thrombosis—*Present* venogram was positive or three of the other parameters were positive *Absent* venogram was negative or three of the other parameters were negative *Equivocal* results in neither of the above two categories

Method of electrode insertion Pacing was performed via the transfemoral route with a No 5 bipolar catheter by a modified Seldinger technique An 18 gauge thin walled needle was used to puncture the femoral vein A guidewire with a flexible tip was inserted through the needle and the needle was then replaced by a short Teflon inner catheter An outer dilating sheath was passed over the inner catheter The guide wire and the inner Teflon catheter were removed leaving only the outer sheath in the femoral vein A woven Dacron catheter with bipolar platinum

and restriction of venous flow might have contributed to the genesis of the thrombosis

The patients with thrombosis did not differ clinically from those without deep vein thrombosis There was no relationship between the occurrence of deep vein thrombosis and the number of venepunctures or the presence of the introducer sheath in the femoral vein Our data are insufficient to derive a definite conclusion regarding the effect of the state of the electrode on the occurrence of thrombosis However none of the eight patients in whom an old sterilized electrode was used demonstrated deep vein thrombosis The occurrence of thrombosis did not seem to be influenced by the duration of pacing although all those with documented deep vein thrombosis had the electrode in place for at least 48 hours

The clinical significance of deep vein thrombosis in these patients is unclear None of our patients developed clinical evidence of pulmonary embolism One patient however, suffered severe temporary disability resulting from thrombosis of the entire deep venous system of the extremity used for pacing Some studies have demonstrated a high incidence of asymptomatic pulmonary emboli in patients with positive fibrinogen leg scan Others have questioned whether asymptomatic clotting in the veins of the lower leg has any serious sequelae

In conclusion deep vein thrombosis is a common complication of transfemoral pacing Although clinical symptoms are infrequent and adverse long term sequelae have not been demonstrated the high incidence of venous thrombosis with transfemoral pacing should be considered before deciding upon the site of entry for a temporary pacemaker Careful prospective analysis of the complications of the use of other entry sites will be necessary in order to make a rational choice Further studies are also necessary to determine if deep vein thrombosis associated with transfemoral pacing can be prevented by anticoagulants or other means

Summary

The incidence of deep vein thrombosis following transfemoral temporary pacing was prospectively assessed in 20 consecutive patients using serial I fibrinogen scanning impedance plethysmography and measurements of fibrin degradation products Four patients underwent venography Of the twenty patients five (25%) had definite evidence of deep vein thrombosis [illegible] demonstrated equivocal abnormalities and [illegible] had no evidence of thrombosis Thrombosis was found only in the legs used for pacing Of the five with deep vein thrombosis one had positive findings in all the noninvasive tests Venography confirmed the diagnosis in the other four one had thrombosis of the femoral vein one had thrombosis of several calf veins and one had thrombosis of both the thigh and calf veins the fourth patient had thrombosis of the entire deep venous system of the leg This latter patient was the only one who had clinical evidence of venous thrombosis The patients with deep vein thrombosis did not differ in clinical characteristics from those without thrombosis There was no relationship between the occurrence of deep vein thrombosis and the number of venepunctures the state of the electrode the presence of the introducer sheath in the femoral vein or the duration of pacing

In conclusion deep vein thrombosis is a common complication of transfemoral temporary pacing and the high incidence of its occurrence should be considered before deciding upon the site of entry for a temporary pacemaker

We are indebted to the staff of the Radiology and Nuclear Medicine Divisions St Elizabeth s Hospital and to the nursing personnel of our coronary care unit for their cooperation We are also grateful to Mary Ellen G Foti and Richard Tucker for their technical assistance

Abnormal in contralateral leg

It is widely employed since it is thought to be relatively free of complications. Despite the frequent use of this approach, reports of deep vein thrombosis of the lower extremities are uncommon. In a retrospective series of 80 patients, Cohen and associates noted the occurrence of deep vein thrombosis in five patients. Of 267 patients with transfemoral pacing reported by Furman and co-workers, only one was found to have had clinical evidence of iliofemoral phlebitis. In several other large series of consecutively paced patients using the transfemoral route, no instance of deep vein thrombosis was noted.

Our study demonstrates a high incidence of venous thrombosis as a complication of transfemoral pacing. The diagnosis was made in five of 20 patients studied. Only one patient had positive findings in all of the noninvasive tests. There were 10 patients with equivocal abnormalities in the noninvasive tests, of whom only four underwent venography; all four had thrombosis of the deep venous system. It is possible that some of the six remaining patients with equivocal results in the noninvasive studies might have demonstrated deep vein thrombosis had venography been performed. Thus the incidence of thrombosis might indeed be higher than the 25% noted. The rarity of reports of thrombotic complications is probably due to the fact that thrombosis is usually not clinically apparent. In our study only one patient had symptoms and physical findings suggestive of deep vein thrombosis.

The occurrence of deep vein thrombosis can be attributed to several factors associated with routine transfemoral pacing. These include venepuncture, the presence of a foreign body, partial venous obstruction, and extended periods of bed rest. Infection can be a cause of thrombosis, but this did not appear to be a factor in these cases. Although our patients remained at bed rest, mobility of the extremity used for pacing was not selectively limited, yet deep vein thrombosis occurred only in the extremity used for pacing. It is noteworthy that all our patients who had venograms had clots distal to the site of entry of the electrode. Thus partial venous obstruction

The effects of vasoconstriction on experimental coronary artery stenosis

William P Santamore, Ph D *

Robert H Cox Ph D
Rita A Carey Ph D
James F Spann M D F A C C
Philadelphia Pa

There is little doubt at present that coronary artery spasm is an important mechanism in the production of angina pectoris Several recent studies have also demonstrated the presence of coronary spasm in preexisting atherosclerotic lesions of the coronary arteries and have suggested [illegible] spasm may be responsible for myocardial [illegible] in some patients [1-11] Implicit in these [illegible] observations is the ability of large proximal coronary arteries to constrict and thereby [illegible] their luminal area From postmortem examination Masen and colleagues demonstrated that areas of stenosis often contain an arterial wall segment which is normal and apparently able to contract To properly study this type of lesion we have developed an in vitro arterial preparation which resembles hemodynamically the coronary lesion in man This model is achieved by obstructing flow through the artery with an intraluminal device which allows a stenosis to be created while still allowing arterial vasoconstriction to occur When the effects of active arterial vasoconstriction were examined in this model in the presence of an otherwide mild fixed stenosis a striking alteration in the hemodynamics of the stenosis was noted In effect the partial stenosis even when mild caused severe occlusion in the presence of arterial vasoconstriction This finding provides some insight into the effects of spasm on coronary flow in man

Methods

The effects of arterial vasoconstriction on stenotic hemodynamics were examined in an in vitro coronary artery preparation An in vitro preparation was used to eliminate distal coronary vasculature neural humoral and systemic effects Eight mongrel dogs (weighing 11.3 to [illegible] kilograms) were anesthetized with sodium pentobarbital (30 mg/kg) and their hearts were exposed through a left lateral thoracotomy The hearts were removed (while still beating) and were placed in a cold physiologic salt solution (5° C) The hearts were kept in the physiological salt solution while the proximal circumflex coronary arteries from the aortic root to the anterior ventricular marginal branch were carefully dissected free from the surrounding tissue All branch arteries along this section of the circumflex artery were ligated and cut distally The distal portion of the circumflex artery was cut [illegible] the anterior ventricular marginal branch and the proximal portion including part of the aortic root was also cut The above procedure required between 30 to 45 minutes to remove the first 3 to [illegible] cm of the proximal circumflex artery After removal four arteries were placed in a physiologic salt solution stored in a refrigerator overnight and studied the next day The remaining arteries were immediately attached to the perfusion appa

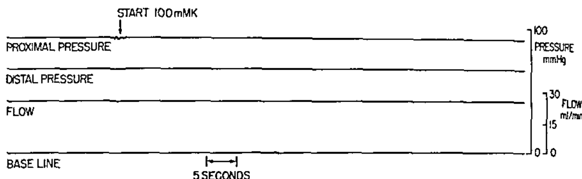

Fig 2 Typical stenotic hemodynamic response to coronary artery vasoconstriction with an external circumferential snare

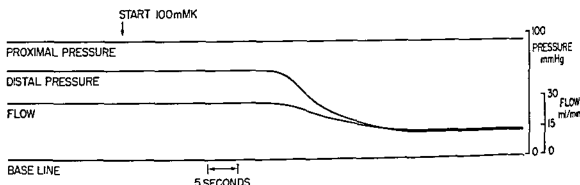

Fig 3 Typical stenotic hemodynamic response to coronary artery vasoconstriction with an intraluminal obstruction

arterial bath solution was drained and was refilled with the 1 5 mMK physiologic salt solution

Next in the presence of an external constrictor the hemodynamic response to arterial vasoconstriction was examined External constriction was achieved by a circumferential snare The snare consisted of a 1 0 silk suture passed around the artery through the polyethylene 160 tubing and attached to a machinist s micrometer This is a commonly used technique to achieve arterial stenosis[1] The artery was perfused with 1 5 mMK physiologic salt solution and the snare was tightened to create a pressure gradient across the stenosis The variables were recorded for 10 minutes to varify stability The perfusate was switched to the 100 mMK salt solution and the variables were recorded for 5 minutes The artery was reperfused with the 1 5 mMK physiologic salt solution the bath solution was drained and refilled with the 1 5 mMK physiologic salt solution The above procedure was repeated two times on each artery studied

Finally the response to arterial vasoconstriction in the presence of internal obstruction was examined Internal obstruction (*Fig 1b*) was achieved by a 3F Fogarty balloon catheter The artery was perfused with the 1 5 mMK physiologic salt solution and the balloon was inflated to create a pressure gradient across the artery Note that the maximum arterial diameter was determined by the perfusion pressure Therefore the balloon did not and could not have created a bulge in the artery while still allowing flow through the artery The Fogarty balloon catheter was inflated with an acrylic solution which solidified within 1/2 hour (*JB-4 Polysciences Inc*) The acrylic solution insured a fixed stable intraluminal obstruction The variables were recorded for 30 minutes to verify stability and to allow the acrylic solution to solidify The perfusate was switched to the 100 mMK salt solution and the variables were recorded for five minutes Provided there was still a perfusion flow the artery was reperfused with the 1 5 mMK salt solution the arterial bath was drained and refilled with the 1 5 mMK physiologic salt solution When the internal obstruction plus the 100 mMK salt solution

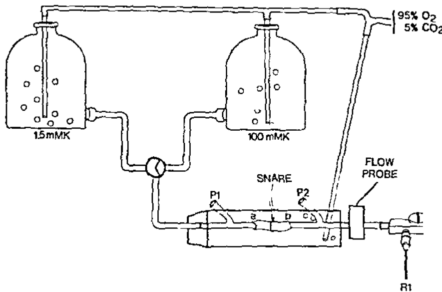

Fig 1a Diagram of in vitro constant pressure perfusion system External constrictor *P1* = proximal pressure *P2* = distal pressure *a* = proximal and *b* = distal points of attachment for artery *P1* – 20 gauge Longdwel needle

ratus and were studied There was no difference in response between the arteries studied after overnight storage in refrigerated physiologic salt solution and those used immediately

The perfusion apparatus (Fig 1*a*) consisted of two pressure reservoirs an arterial bath and fixed distal resistance One reservoir contained a 1.5 mMK physiologic salt solution (composition in millimoles per liter 122 0 NaCl 25 0 $NaHCO_3$ 1 2 NaH_2PO_4 1 2 $MgSO_4$ 1 5 KCl 2 5 $CaCl_2$ and 10 pyruvic acid pH = 7 42) while the other reservoir contained a 100 mMK solution (composition in millimoles per liter 24 NaCl 25 $NaHCO_3$ 1 2 NaH_2PO_4 1 2 $MgSO_4$ 100 KCl 2 5 $CaCl_2$ 10 pyruvic acid pH = 7 42) The arterial bath was filled with the 1.5 mMK physiologic salt solution All solutions were maintained at 37° C and were equilibrated with a gaseous mixture of 95% O_2 5% CO_2 The distal resistance was a 20 gauge Longwel needle Proximal and distal pressures were measured with pressure transducers (Statham) Perfusion flow was measure with an extracorporeal flow probe (Biotronex) This flow probe was calibrated by a timed collection in a graduated cylinder The data were recorded on a multichannel recorder (Electronics for Medicine model DR-8)

The artery was placed in the bath solution attached to point a and b (Fig 1*a*) and stretched to its in vivo length The reservoir pressure was applied to the arterial segment and the artery was allowed to stabilize for two hours The reservoir pressure and the arterial length were kept constant throughout the experiment

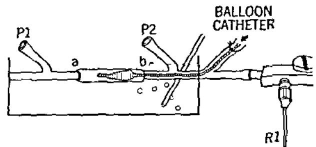

Fig 1b Diagram of in vitro constant pressure perfusion system Internal obstruction Abbreviations and symbols same as in *Fig 1a*

Prior to creating the stenosis the hemodynamic response to arterial vasoconstriction was examined The distal stopcock was opened and the perfusate was allowed to flow through the artery The variables were recorded while the artery was perfused with the 1 5 mMK physiologic salt solution After five minutes the perfusate was then switched to the 100 mMK salt solution and the variables were recorded Changing from a 1 5 mMK solution to a 100 mMK solution causes consistent coronary artery vasoconstriction After five minutes the artery was reperfused with the 1 5 mMK physiologic salt solution and the

vasodilation on pressure and flow in a stenosis that was created with the intraluminal balloon After obtaining the response described in Fig 3 the perfusate was switched back to a 1 5 mMK physiologic salt solution This reperfusion resulted in a return of flow and an increase in distal pressure thus allowing the initial stenotic hemodynamics to be restored It should be pointed out that if the flow reduction caused by arterial vasoconstriction was severe (flow less than 1 ml/minute) reperfusion was ineffective in reestablishing the initial conditions because the 1 5 mMK solution could not reach the stenotic site In these experiments nitroglycerin (0 4 mg) was added to the arterial bath solution This reestablished the initial stenotic hemodynamics

Table I summarizes the results from the eight coronary arteries studied Table I is based upon eight observations with no constriction 16 observation with external constriction and 24 observations with an internal obstruction The diameter data are from two experiments Prior to the creation of an arterial steno is vasoconstriction had no significant effect on the measured and calculated variables Similarly with arterial stenosis produced by an external circumferential snare arterial vasoconstriction had no significant effect on the measured and calculated variables In striking contrast with stenosis produced by an intraluminal balloon catheter arterial vasocon striction caused significant hemodynamic changes Distal pressure flow and di tal diameter decreased and the stenotic resistance increased markedly Thus internal obstruction potentiated the effects of arterial vasoconstriction causing significant hemodynamic chan

Discussion

This is the first experimental model where a reduction in flow through the coronary artery has been achieved by proximal coronary artery vasoconstriction Other animal experiments h e shown a coronary flow reduction caused by vasoconstriction along the entire coronary vascula ture However this is the *only* animal model where proximal coronary artery con triction alone (vasoconstriction along the first 3 cm of the coronary artery) has been able to reduce flow through the vessel In light of the current cli ical interest in coronary artery spasm where the major pathophysiological mechanism appears to be an abnormal contraction in the proximal coronary artery this animal model is an impor tant first step in understanding some of the hemodynamics of coronary artery spasm

This study demonstrates the striking hemodynamic effect of arterial vasoconstriction when a partial luminal obstruction is pre ent Neither the arterial vasoconstriction alone in the normal vessel nor the stenosis alone cau ed a significa t

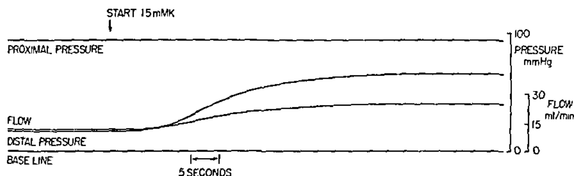

Fig 4 Typical stenotic hemodynamic response to coronary artery vasodilation with an intraluminal obstruction

caused the perfusion flow to cease nitroglycerin (0 4 mg) was added to the bath This always caused a relaxation of the artery and reestablished the normal perfusion flow The above procedure except for inflating the balloon was repeated three times on each artery studied

In the last two experiments the diameters of the circumflex artery proximal and distal to the stenotic site were measured with a calibrated eyepiece (magnification 7×) The diameters were measured just before and during the perfusion with the 100 mMK salt solution

The stenotic resistance was calculated as the pressure gradient across the stenosis divided by the flow throught the stenosis [1] the pressure gradient being the proximal pressure minus the distal pressure The distal resistance was calculated as the distal pressure divided by the flow The stenotic and distal resistances were only calculated when the flow was greater than 1 0 ml/minute In each data group the mean and the standard error of the mean were determined for the proximal pressure distal pressure flow stenotic resistance and distal resistance Statistical significance was determined by comparing the 15 mMK response to the 100 mMK response by the Student s t test [1]

Results

Fig 2 shows the effects of coronary artery vasoconstriction on pressure and flow in the artery An initial stenosis was created with an external circumferential snare With a 1 5 mMK physiologic salt solution perfusing the artery the initial *stenosis was established and allowed to* stabilize for ten minutes The perfusate was switched to a 100 mMK salt solution indicated *by the arrow* in Fig 2 The 100 mMK solution was

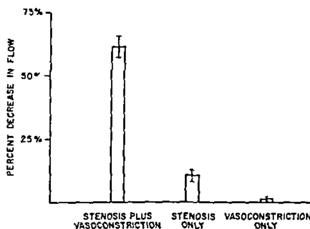

Fig 5 Diagram showing synergistic effects of stenosis and vasoconstriction on reducing flow

used to induce arterial vasoconstriction As can be seen in Fig 2 maximum arterial vasoconstriction caused no observable effects on the flow through and the pressure across the stenosis produced by an external circumferential snare

Fig 3 shows the effects of coronary artery vasoconstriction on pressure and flow in a stenosis that was created with an intraluminal Fogarty balloon catheter With a 1 5 mMK physiologic salt solution perfusing the artery the initial stenosis was established and was allowed to stabilize for 30 minutes The perfusate was then switched to a 100 mMK salt solution As can be seen in Fig 3 arterial vasoconstriction severely reduced the flow through and increased the pressure across the stenosis Thus *stenoses created by* internal obstruction were extremely sensitive to arterial vasoconstriction

flow change but when present together they act synergistically to produce a marked reduction in the arterial lumen, a large pressure gradient, and a significant reduction of flow (see Fig. 5).

Conversely, with partial stenosis created by a circumferential snare, subsequent arterial vasoconstriction had little effect on stenotic hemodynamics. The initial stenotic resistance, flow, and distal pressure (see Table I) were almost identical for stenoses created by either an external snare or by an intraluminal obstruction. Yet with external snare, arterial vasoconstriction was ineffective. Conceivably, the external snare shortened the circumferential vessel fibers to a maximal degree so that no further shortening was possible by vasoconstriction. This observation may be relevant to the clinical situation where although two patients may have a similar degree of stenosis, only one patient will exhibit coronary artery spasm.

With the internal obstruction, arterial vasoconstriction could have increased the hemodynamic severity of the stenosis by a slight reduction in the vessel radius at the stenotic site. In an otherwise normal vessel a 5% reduction in radius would cause approximately a 10% reduction in vessel area. With an initial stenosis of 85 to 90%, a 5% reduction in vessel radius can occlude the artery. Also, the Bernoulli Principle might increase the effectiveness of the vasoconstriction. According to Bernoulli's equation, the pressure by the stenosis is reduced.[1] This stenotic pressure decrease would allow the vessel to constrict even further; the lower the intraluminal pressure, the greater the resulting vessel radius decrease for the same vasoconstriction stimulus.

There is increasing evidence in man that some episodes of angina pectoris may be caused by arterial spasm superimposed on the atherosclerotic stenosis of a major coronary artery. In these patients, coronary artery spasm can be induced by intravenous ergonovine maleate or by hyperventilation combined with tris buffer infusion and can be relieved by nitroglycerin. Coronary angiograms have shown a decrease in vessel diameter or actual closure of the vessel during angina attacks in some patients. Nitroglycerin caused these vessels to dilate. These clinical studies suggest that angina pectoris and myocardial infarction are in part associated with dynamic spasm becoming additive to fixed lesions of the coronary arteries in some patients.

Indeed, Maseri and co-workers have used postmortem studies to demonstrate that areas of atherosclerotic stenosis often contain a wall segment which is normal and apparently able to contract. In this study, stenosis created by an intraluminal balloon catheter exhibited characteristics similar to the clinical lesion; the arterial wall is able to contract, arterial vasoconstriction increased stenotic severity, and dilation decreased stenotic severity. We believe that this type of response is a reasonable model for at least some of the stenotic lesions found in coronary artery disease.

In our experiments, if the flow reduction after arterial vasoconstriction was severe, then reperfusion with the 1.5 mMK physiologic salt solution was ineffective in relieving the spasm, possibly because the 1.5 mMK solution never reached the stenotic site. If arterial spasm in man resulted in temporary total occlusion with absence of flow, the vasoconstriction may become irreversible because removal of the vasoconstricting stimulus, if it was blood borne, would be impossible.

Summary

In summary, we have examined the response to arterial vasoconstriction in an in vitro coronary artery preparation. Without a preexisting stenosis, arterial vasoconstriction had minimal hemodynamic effects. Similarly, with a stenosis created by a circumferential snare, arterial vasoconstriction had minimal hemodynamic effects. In striking contrast, with a stenosis created by intraluminal obstruction, arterial vasoconstriction dramatically increased the hemodynamic severity of the stenosis. The use of an intraluminal obstruction provides a useful animal model for examining hemodynamics in coronary artery disease and has provided some insight into the effects of vasoconstriction on coronary artery hemodynamics. Obviously, this is an experimental study, and care must be taken in extrapolating these results to diseased human coronary arteries.

The authors gratefully acknowledge the technical assistance of Thomas Vinciguerra, David Santamore, and John Michele.

Clinical features and the usual laboratory data as well as cardiac catheterization findings may fail to differentiate right ventricular endomyocardial fibrosis (RVEF) from Ebstein s anomaly

Since RVEF is correctable by surgery at least potentially differentiation of these cases from Ebstein s anomaly is important and the latter also may require surgical intervention

Accurate bedside diagnosis of RVEF is some times possible however tricuspid regurgitation occasionally associated with a tricuspid diastolic flow may be confused with rheumatic heart disease[1]

This report is concerned with a case of RVEF which was operated on with a preoperative diag nosis of Ebstein s anomaly

Case History

A T a 20 year-old man was admitted in January 1975 with a six year history of exertional dyspnea, progressive swelling of the face and abdomen slight bilateral ankle edema with small varicose veins and moderate mucocutaneous cyanosis

There was neither history of rheumatic fever during child hood nor cyanosis at birth Conjunctivae and oral mucosa were congested jugular veins were engorged and the top of the venous column was seen at mandibular angle at 45 degree trunk elevation without prominent pulsation Pulses were of low volume and blood pressure was 100/70 mm Hg The patient was afebrile Kussmaul s sign and paradoxical pulse were absent

Division of Pathology Heart Hospital

The precordium was quiet The first heart sound was widely split with very prominent second component A soft pansystolic murmur was initially heard at the patient s first physical examination at the right lower sternal border which was accentuated by inspiration At his second admission in 19 when his congestive heart failure was severe this murmur could hardly be heard without any change in inspiration Right ventricular gallop was present at both admissions A and P were physiologically split and were normal in intensity

A few bilateral basal crepitant rales were present initially which cleared soon following digoxin and diuretic therapy A moderate amount of ascites was present The liver was enlarged 4 cm below the right costal margin

Hepatic systolic pulsation which was present at his first admission in 19 5 was not felt at the second admission and it was thought that the liver was slightly smaller

Slight pitting edema and many small varicose veins were observed mostly around the ankles Moderate clubbing was present

Electrocardiogram and chest roentgenogram The electrocardiogram showed atrial fibrillation and a pattern of incomplete right bundle branch block (RBBB) (Fig 1) A chest x ray revealed an enlarged balloon shaped heart with a very prominent right atrium and a narrow vascular pedicle The enormous cardiac shadow contrasted with oligemia of the lung fields (Fig 2)

Echocardiogram The first echocardiogram was interpreted as simultaneous tricuspid and mitral valve echograms Two leaflets of the tricuspid valve could be seen during the entire cardiac cycle simulating a pattern of tricuspid stenosis The time difference between the mitral and tricuspid closure was too long almost half a cardiac cycle Scanning from the aorta to the mitral area revealed normal aorto mitral continuity and the anterior wall of the aorta was in continuation with what we thought was the tricuspid valve (Figs 3 and 4)

Catheterization data and intracardiac electrocardiogram Catheter manipulation did not induce significant arrhythmias Atrial septal defect or patent foramen ovale was not found Entering the right ventricle and pulmonary artery was not easy Leftward displacement of the tricuspid valve was noted during angiography and pressure curve recording (Fig 5) Arterial oxygen saturation was low (82%) Mean right atrial pressure was high (24 mm Hg) Right ventricular

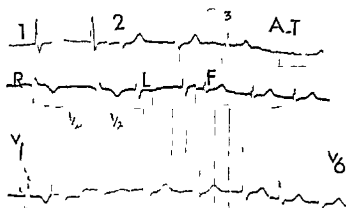

Fig 1 Atrial fibrillation and a pattern of incomplete right bundle branch block are shown in this ECG tracing

Fig 2 A chest x ray shows the enlarged balloon shaped heart with a narrow pedicle and a prominent right atrium

systolic pressure was 40 mm Hg with a high end diastolic pressure of 24 mm Hg The right ventricular pressure curve had a dip and plateau pattern (Fig 6) Attempts to record a His bundle electrocardiogram failed The simultaneous pressure and intracardiac electrogram was suggestive of Ebstein s anomaly (Fig 7) Pressing the electrode catheter tip against the endocardium produced marked S T segment elevation (Fig 8)

Operative and pathologic findings The heart was quite enlarged mostly due to the huge right atrium and lacked the typical rocking motion seen in patients with Ebstein s anomaly There was no atrial septal defect or patent foramen ovale The anterior leaflet of the tricuspid valve was wide and floppy spared from extensive shrinkage thickness and distortion but the posterior and septal leaflets had downward displacement due to the traction by fibrotic tissue The entire RV cavity as well as the outflow tract was covered by a thick dense layer of fibrosis During resection of the dense right ventricular fibrotic layer the interventricular septum was ruptured and repaired The tricuspid valve was replaced by a porcine prosthetic valve The patient did not do well after the operation and died because of low cardiac output syndrome mostly due to intractable right sided failure At autopsy the left side of the heart al o was li htly involved (Fig 9)

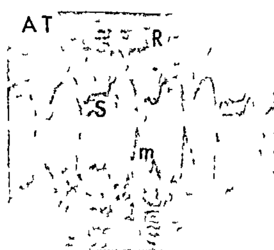

Fig 3 Mitral echogram of patient A T showing markedly paradoxical septal motion

Comments

The incidence of pure right sided endomyocardial fibrosis is not clearly known and has been reported in different articles [3] in 10% to about 50% of patients suffering from endomyocardial fibrosis

On the right side the process may be more massive than in the left ventricle and may obliterate most of the right ventricle but it still usually spares the infundibulum and pulmonary valve although the infundibulum was involved in our case

Clinical consideration When endomyocardial fibrosis involves the papillary muscle chorda and leaflets of the tricuspid valve tricuspid incompetence is common often with a huge a[4] even aneurysmal dilatation of the right atrium.

Right sided endomyocardial fibrosis has a slowly progressive course leading to right sided congestive heart failure in contrast to left sided c the combined form of the disease which rapidly leads to a fatal outcome [5] The onset of symptoms is quite insidious causing effort intolerance secondary to low cardiac output mild cyanosis peripheral edema hepatomegaly and ascites Small varicosities may be seen over the legs mostly around the ankles due to long stand high venous pressure

The following clinical findings which were present in our patient are classically mentioned in Ebstein s anomaly[6]

1 An unusual facial coloration is occasionally present resulting in a red cheeked or violaceous appearance

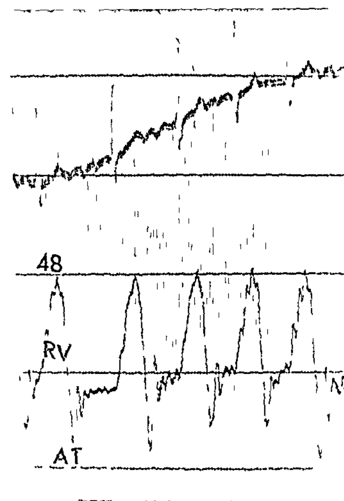

Fig 6 A right ventricular pressure curve illustrates a dip and plateau pattern and high end diastolic pressure

Conduction disturbances were seen in 19 of the 95 cases reviewed by Ratzner and co workers Bundle branch block and intraventricular conduction delays were the most frequent occurrences not surprising in view of the endomyocardial thick fibrotic lesion In endomyocardial fibrosis unlike fibroelastosis the normal layers of the endocardium are destroyed and are replaced by thick scar tissue although only one patient out of 21 patients reviewed showed the pattern of incompelete RBBB This is in contrast to Ebstein s anomaly in which 75% to 80% of these patients have a complete or incompelete RBBB although this is considered atypical because of the low voltage and polyphasic configuration and it has no specific or diagnostic feature

Echocardiography Simultaneous recording of the tricuspid and mitral valve echograms is not unusual in Ebstein s anomaly Decreased tricuspid diastolic closure slope (E F slope) is one of the echocardiographic features of this anomaly although the amplitude of what was thought to be two leaflets of the tricuspid valve was less than mitral valve motion and this is not the case in Ebstein s malformation According to Lundstrom [13] an echo from the posterior or septal tricuspid leaflet is rarely recorded in Ebstein s anomaly Delayed tricuspid closure is considered to be the most consistent echocardiographic feature of the abnormally positioned tricuspid valve but its continuation with the anterior wall of the aorta cast doubt on our previous belief and apparently this was the interventricular septum with markedly exaggerated paradoxical motion (Fig 3) Although it is said that all patients with Ebstein s malformation have type B septal motion (the septal echoes become flattened during systole instead of anterior motion in type A) five out of 19 patients reported by Lundstrom had type A septal motion Therefore Ebstein s anomaly could not be ruled out by this finding

Interpretation of catheterization data and electrophysiological studies

Leftward displacement of the tricuspid valve has been considered a valuable sign in Ebstein s anomaly and this was also apparent in our patient The apex of the right ventricle (RV) was obliterated by scar tissue and the RV cavity was shrunk and contracted This was confirmed by RV angiography, which showed the absence of the usual apical cavity initially thought to be the RV proper of Ebstein s anomaly (Fig 5)

Atrial septal defect or patent foramen ovale which was present in 14 out of 65 cases with Ebstein s anomaly, was not found.[1] In a report by Kumar and associates [5] seven out of 55 patients with Ebstein s malformation developed transient tachycardia this did not happen in our patient Difficulty in entering the RV and pulmonary artery [1] low arterial O saturation and high mean right atrial and RV end diastolic pressure may be encountered in both entities. The RV pressure curve had a dip and plateau pattern simulating constrictive pericarditis but this may be seen in chronic right sided disease pericardial effusion primary pulmonary hypertension and with intracardiac tumor [1, 11] This appearance could be due to deep intramyocardial penetration of the fibrotic process causing an early diastolic

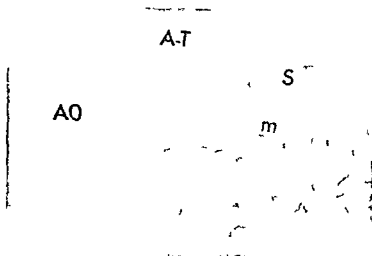

Fig 4 Echogram of the patient showing aorto mitral continuity

2 The relatively unimpressive jugular venous pulsations present because of the huge right atrium and the toneless atrialized right ventricle

3 Absence of a systolic impulse over the body of the right ventricle

4 Early systolic murmurs in Ebstein s anomaly generally do not increase during inspiration despite their tricuspid origin

In reviewing 10 patients with Ebstein s anomaly Crew and associates have found that the only constant anomaly was abnormally wide splitting of the first sound with accentuation of the delayed component This abnormal sound was thought to be caused by delayed closure of the abnormally large anterior leaflet of the tricuspid valve The intensity of the sound despite a hypodynamic right ventricle is of interest in relation to the mechanism of heart sounds

According to Fontana and colleagues the systolic sound may not be a closure sound since it is present in cases with considerable tricuspid regurgitation where the leaflets may not approximate at all The sound is probably more related to the termination of motion of the anterior leaflet which was larger than usual in our patient

Electrocardiography In studying the electrocardiographic findings in 30 case of endomyocardial fibrosis[a] no specific diagnostic pattern was found except for an abnormal P wave (P mitrale or pulmonale) a low voltage QRS and nonspecific changes in T waves

Atrial flutter or fibrillation are seen in only 2% to 5% of patients with Ebstein s anomaly while

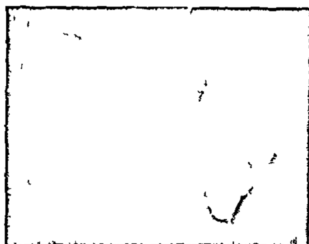

Fig 5 Right ventricular angiogram shows leftward displacement of the tricuspid valve with a dilated right atrium

six of 11 patients with endomyocardial fibrosis had this rhythm Our patient had both atrial fibrillation and a pattern of incompelete right bundle branch block (Fig 1)

Although our patient did not have episodes of supraventricular tachyarrhythmias which are well known in Ebstein s anomaly a high incidence of arrhythmias is reported in endocardial fibroelastosis probably due to degenerative changes in the cells of the cardiac ganglia We are not aware of this histologic change in endomyocardial fibrosis The absence of supraventricular tachyarrhythmias in our patient could be due to atrial fibrillation which is rare in Ebstein s anomaly and is rather common in endomyocardial fibrosis

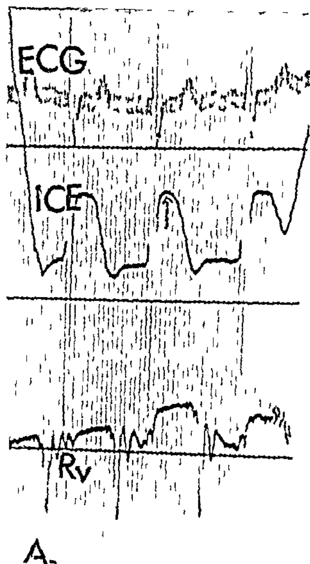

Fig 8 Intracardiac electrogram recorded while pressing the electrode catheter tip against the right ventricular endocardium damping the pressure and producing a contact potential (arrow)

Fig 9 At autopsy a thick layer of right ventricular endomyocardial fibrosis was found

retrospect was considered to be probably due to a thick layer of fibrosis covering the septal surface of the right ventricle

Conclusion

A differential diagnosis between these two rare entities which require different therapeutic approaches is important The reported results of surgical treatment of RVEF are encouraging while in Ebstein s anomaly this is not the case and one should be more conservative in sending patients for operation Clinical features and chest roentgenograms could be quite similar and electrophysiologic studies may be misleading Cineangiograms rather than rapid sequence films seem to be very reliable for this differentiation

Summary

A case of right ventricular endomyocardial fibrosis simulating Ebstein s anomaly is described The clinical features chest x ray electrocardiogram echocardiogram intracardiac electrogram and the angiogram were all compatible with Ebstein s malformation A correct diagnosis was subsequently made in the operating room Reasons for the difficulties in the differential diagnoses of these two entities are discussed

We wish to thank Dr Jamu Shakibi for his advice in the preparation of this manuscript and Dr Harvey Feigenbaum for interpreting the echocardiogram

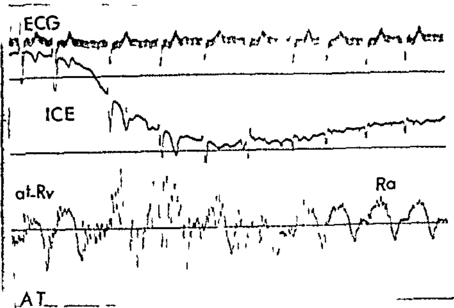

Fig 7 Simultaneous intracardiac electrogram *(ICE)* and pressure recording An intracavitary potential is recorded immediately after withdrawing the catheter from the right ventricle presumably into the atrialized right ventricle *(at RV)*

recoil after termination of RV contraction (Fig 6) In severe RVEF the right ventricular apex is mostly obliterated and the infundibulum is dilated with tricuspid regurgitation pressure pulses from the pulmonary artery the RV and the right atrium are distorted and resemble each other This entity could be quite similar to Ebstein s anomaly when the pressure curves are identical In our case the pressure curves were similar but not identical (Fig 7) Therefore local ization of the catheter tip by pressure pulse could be inaccurate It is known that when an electrode catheter touches the normal endocardium there will be an S T segment elevation which is called "contact potential rather than current of inju ry [9] Some authors believe that this contact potential may be almost absent or minimal when the electrode touches the area which is covered by a thick layer of endocardial fibrosis Significant S T elevation was present in our right ventricular intracardiac electrocardiogram in spite of a dif fuse and thick layer of RV endomyocardial fibro sis (Fig 8) Probably by repeated catheter manip ulation and positioning we could also get right ventricular pressure and ECG pattern without S T elevation According to Sodi Pallares this contact potential should be recorded when the atrialized right ventricle is also touched by the catheter tip whereas contact with the true atrial endocardium should produce elevation of the P Q segment Although S T segment elevation was produced in only one out of eight patients studied by Lowe and co workers this change was clearly shown in our patient Upon withdrawing the catheter when the pressure dropped and the pressure curve changed slightly hand injection of dye proved that the catheter tip was out of the RV In this position the QRS voltage decreased markedly but a ventricular pattern (rs) remained There was no S T segment elevation (Fig 7)

Watson[18] has mentioned many pitfalls in intra cardiac electrocardiography and the reasons for having false positive and false negative diagnoses of Ebstein s malformation It has been demon strated that a normal intracardiac electrocardio graphic and pressure relationship might be pres ent when the catheter is withdrawn across the anterior ricuspid leaflet or true annulus at the midatrial level When the right ventricular cavi ty is obliterated or contracted due to RVEF the difference in the magnitude as well as the direc tion of the unbalanced electrical forces on two sides of the high ventricular septum may cause an electrode catheter to continue to record ventricu lar potentials after it entered the right atrium

Failure to record His bundle deflection in

Congenital pericardial defect associated with cardiac incarceration: Case report

Reiko Saito
Futsumi Hotta
Tokyo, Japan

A congenital defect of the pericardium is rare. Since Columbus reported the first case in 1559,[1] only around a hundred cases have been found in the whole world. Though such symptoms as palpitation and exertional chest pain occasionally occur, the overwhelming majority of the patients remain asymptomatic, and the defect is discovered by chance in a postmortem examination or operation.

A young child with the congenital pericardial defect who died of incarceration of the left ventricle was seen at the Tokyo Medical College Hospital. The clinical course and autopsy findings are described below.

Case report

This 4 year old boy had been healthy since birth. In the evening of April 19, 1979, he had a fight with his 7 year-old sister over a book and accidentally struck his chest with his own fist. Chest pain started immediately after this episode which was agonizing and was accompanied by gradually increasing facial pallor. He was admitted to a nearby hospital 30 minutes after the accident. Chief findings on admission were as follows: ... n iousness lethargic, respiration rate 44/minute, pulse rate 1?6/minute, blood pressure 98/66 mm H..., body temperature 3.. ... C, ... s t lic murmur over the apex and the liver palpable for ... m. Peripheral blood count showed a neutrophilia (whc ...,800 and ...% neutrophils). ECG recording taken immediately after admission showed a strong right axis d... ... ... ation of the ST segment as we... ... ... in Leads II, III and aV..., from which ... ... the inferior wall through the apex ... ... A chest x-ray disclosed de...ati... ... the h...ar... ... ... n, left abnormal protrusion of the left third and fourth arch, and ... ... lung marking (Fig. 2, *left*).

After admission, chest pain persisted, the ... became worse, and the patient sometimes cried ... Systolic blood pressure fell to 64 mm Hg. Oxygen ther..., adrenocortical hormones, cardiotonics, and ... ... bonate solution were used. Twelve hours after onset the p... was 110/minute, irregular and faint, while the ... cyanotic. ECG recordings taken 13 hours after onset showed that the ST segment, contrary to the previous ..., ... depressed in Leads II, III, and aV..., and was elevated in Leads I, aV$_L$, and V... to V..., which suggested ischemia centering in the lateral wall (Fig. 1B). The patient was referred to our hosp... at 2 P.M. on April 20, 1979, at which time consciousness ... lethargic, measurement of blood pressure was not ..., pulse rate was 80/min., respiration rate was .../min, and ... generalized cyanosis as well as edema of the face and ... were noted. Chest x-ray revealed more marked protrusion of the left third and fourth arch (Fig. 2, *right*). The patient died ... minutes after admission, 19 hours after onset.

Gross findings at autopsy were as follows: A tumor of ... egg size was observed on the left side of the heart on ope... the chest which, when the heart was removed, was ... to be the left ventricular wall protruding through the ... created by a partial defect of the pericardium (3.5 x 4.5 cm ...) that is, the left ventricle was incarcerated. The ... wall at the borders of the incarceration was squeezed ... presented a picture of a clear deep entrapment, ... posterior wall. The incarcerated part was clearly differ... from the normal part in color tone. The part ... incarceration included the apex, the posterior and lateral ... and a portion of the anterior wall of the left ventricle (Fig. 1 ... and B).

Besides the aforementioned abnormalities, ... ml of ... fluid was accumulated only in the left thoracic ca... and ... liver and lung were congested.

Histopathologically, the peripheries of the pericardial de... were marked by conspicuous thickening of the ... pericardium and by an increase in collagen fibers (Fig. 4) ... myocardium in the incarcerated part was marked ... in general and showed congestion and hemorrhage ... necrosis here and there besides being infiltrated ... cytes. Myocardial necrosis was more conspicuous on ... anterior than on the posterior wall. Around the ... part, myocardial infarction was more severe than ... healthy part (Fig. 5).

Subjective symptoms are rare with either type of the defect In the left extensive defect however absence of the support for the left sided heart sometimes leads to such complaints as palpitation sensation of throbbing heart and chest pain at the time of exertion and the heart is frequently found to be deviated to the left on x ray examination The left partial defect is sometimes discovered from an abnormal shadow in the chest (protrusion of the left second arch) due to deviation of the left atrium Very rarely the left atrium and left ventricle protrude through the partial defect and the patient dies from incarceration Robin and associates reported their successful life saving surgery for incarceration of the left atrium that was discovered while performing emergency surgery for sudden shock in a 28 year old man with the left partial pericardial defect If a part of the left ventricle is incarcerated through the defect the coronary artery is compressed, with resultant myocardial infarct and death The aforesaid accident is extrem rare and so far has been found only in three ca in the literature including one reported Boxall in 1887[5] Onset was sudden and de occurred in a relatively short time in all th cases (Table I)

In the present case the pericardial defect w located in the region of the left ventricle and w large enough to permit protrusion of the l ventricle which constituted the primary fac for incarceration of the left ventricle Histolo cally the inner side of the borders of the perica dial defect was thickened and a flap like p dial defect was thickened and a flap like pe between the outer and the inner side was sca tered with fat while the outer membrane co tained markedly fibrotic small vessel here there The above changes suggest that a mech ical stress had been applied to the said tissue f long time The left ventricular wall showed a de

Discussion

Congenital pericardial defect is a relatively rare congenital anomaly originating in agenesis of the pericardium and parietal pleura According to Perna a defect of the pericardium and pleura results if the left common cardiac vein (Cuvier s duct) atrophies early around the eighth embryonic week since nutrition of the pleuropericardial membrane separating the pleural and the pericardial cavity is disturbed by such an early obliteration Because the right Cuvier s duct remains as the superior vena cava this anomaly is usually found on the left side It may be extensive or partial depending upon the size of the defect

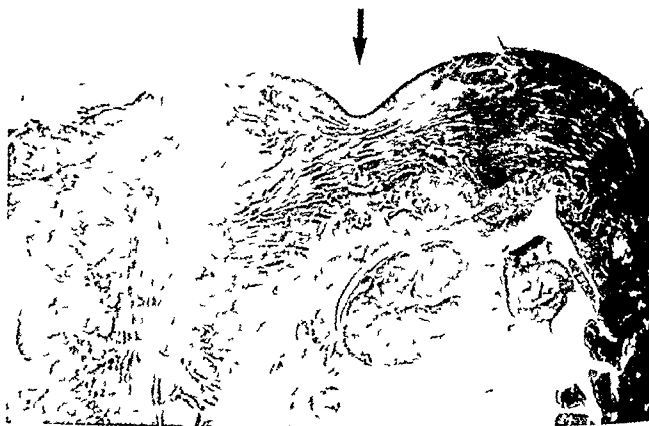

Fig 5 Histological view of the myocardium of the left ventricle *Left* normal *Right* the incarcerated part that shows hemorrhage and necrosis *The arrow* shows the impression produced by the border of the pericardial defect

through fixing of the heart with the use of Teflon mesh These surgical treatments however must be preceded by preoperative diagnosis for which the aforesaid diagnostic procedures are useful

Summary

1 A 4 year old boy with the congenital partial defect of the left pericardium who presented with myocardial infarction died of incarceration of the left ventricle

2 This is the fourth reported case of death from this anomaly in the world

3 Because this anomaly occasionally causes sudden death it is important to diagnose the condition while the patient is alive

We are deeply grateful to Prof Teruo Honda for reviewing the manuscript Our sincere gratitude is also expressed to Dr Shigeru Masuda of the First Pathology Laboratory of Tokyo Medical College Dr Ryozo Okada of Juntendo University as well as Dr Nobuk Yanagisawa and Dr Takashi Wada of Kokusai Shinzen H for their kind advice

sion produced by a ligament on the poste le from which that part of the ventricular as considered to have repeatedly passed h the pericardial defect to protrude or ack for a considerably long time Applica an external force to the chest in the form tusion was considered to have precipitated versible protrusion of the ventricular wall ch ischemia of the inferior and posterior of the left ventricle occurred first then s return was inhibited as the anterior wall ushed outside in turn and congestion rhage and decrease in arterial flow ensued t order with the resultant severe cardiac and death

recordings showed elevation of the ST nt in Leads II III and aV_F immediately admission and marked elevation of the ST nt in Leads I aV_L and V to V 13 hours that The aforesaid changes in the ECG st that myocardial necrosis progressed from the lateral to the anterior wall This finding agreed with the histological findings

In the present case a systolic murmur was heard after the occurrence of incarceration This heart murmur seemed to have resulted from functional failure of the papillary muscle due to myocardial necrosis and subsequent mitral insufficiency In all the previously reported cases of death from cardiac incarceration mentioned above a systolic murmur was noted

Since sudden death occasionally occurs with the congenital pericardial defect it is important to diagnose the condition while the patient is alive Diagnosis is generally made by chest x ray ECG echocardiography and artificial pneumothorax A jugular phlebogram is helpful as a safe test causing little pain

The treatment of the congenital pericardial defect consists of closure of the defect by direct suture or fixing of the heart Kubo and colleagues reported that they obtained good results

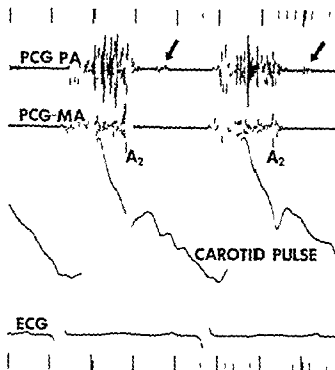

Fig 1 Phonocardiogram of pulmonary area *(PCG PA)* and mitral area *(PCG MA)* A harsh systolic murmur and a diastolic sound *(arrow)* were recorded The murmur continued beyond the aortic component of the second heart sound *(A_2)* and the sound was separated approximately 150 msec from A Time intervals equal 40 msec

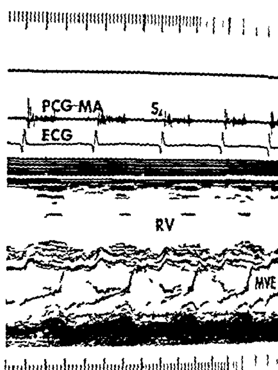

Fig 2 Echophonocardiogram showing the dilatation of the right ventricle *(RV)* The interventricular septum is abnormal in that it moves anteriorly in early systole *MVE* = mitral valve echogram Vertical distance between dots is 1 cm S_4 = fourth heart sound.

the tricuspid orifice to the right atrium Pulmonary regurgitation was noted During levophase the left side of the heart was normal. There was no intracardiac shunt

Operative findings Surgery performed with the diagnosis of right ventricular tumor A palpable thrill during systole was present over the right ventricular outflow tract A transverse right outflow tract incision was made exposing the pedunculated intracavitary tumor The tumor was 6 × 3 × 2.5 cm in size and 27 g in weight (Fig 6) It was easily delivered from the pulmonary artery through the pulmonary valve which appeared to be normal The attachment was entirely excised including the full thickness of the anterior right ventricular wall The pathological diagnosis was myxoma The patient had an uneventful recovery

In a postoperative echophonocardiogram the tumor echoes were no longer visible in the right ventricular outflow tract The right ventricular dimension was still increased, but a normal pulmonary valve was recorded No adventitious systolic or diastolic sounds were recorded

Angiographic analysis In order to investigate the relationship between the motion of the tumor and the diastolic sound we traced frame by frame the configuration of the tumor provided by cineangiography (Fig 7) In mid-diastole the tumor fell back into the ventricle and reached its most anterior and inferior position where it could be seen to strike the right ventricle in the lateral angiographic views (arrow in Fig 7) In presystole when the right ventricle remained dilated atrial contraction forced the tumor upwards, toward the pulmonary valve and with the subsequent ventricular contraction part of the tumor was propelled through the valve retaining this advanced position throughout systole The pulmonary valve could not be seen clearly through the cardiac cycle but in diastole the tumor mass was clearly located below the valve

Discussion

Myxoma of the right ventricle is extremely rare compared to its occurrence in the right or left atrium We could find only 33 reported cases in the literature[3] [4] These consisted of 18 males and 15 females with ages of 2 months to 65 years averaging 26.8 years Clinical findings as well as physical manifestations are mainly dependent on the position and size of the tumor within the right ventricle Most myxomas are movable or pedunculated and sometimes have a long stalk except for one adult case[5] and two infant cases in which the tumor cells infiltrated the myocardium Right ventricular myxomas usually originate in the free wall or in the interventricular septum and in some cases in the tricuspid valve the pulmonary ring[6] or the valve

Right ventricular myxoma Case report and review of phonocardiographic and auscultatory manifestations

Yoshiyuki Hada M D
Carla Wolfe
Gordon F Murray M D
Ernest Craige M D
Chapel Hill N C

Tumors of the right ventricle are extremely uncommon We recently observed a patient with a right ventricular myxoma whose physical find ings included a peculiar sound in mid diastole The purpose of this case report is to describe the pathogenesis of this vibration a tumor plop as determined by combined echo and phonocardio graphic studies supplemented by cineangiogra phy Previously reported cases are reviewed with special reference to phonocardiographic and aus cultatory findings

Case Report

A 28-year old man was admitted to North Carolina Memo rial Hospital for evaluation of a heart murmur The patient had been in good health until two years previously At that time he noticed a pressure" feeling in his chest when he lifted moderately heavy objects or climbed stairs He also noted palpitations and shortness of breath He had no diaphoresis, nausea or pain He had a history of having been athletically inclined and instituted a program of weight control and physical conditioning in order to overcome his symptoms. He lost 20 pounds from 190 to 170 but was unable to diminish the palpitations and dyspnea In June 1979 when he was jogging as he had done on many occasions he had a sudden dizziness followed by syncope of brief duration This was accompanied by palpitation and a flushed feeling with dyspnea He con sulted a local physician who noticed a heart murmur and referred him to our hospital The patient had no history of rheumatic fever frequent respiratory infections, or cyanosis. Past and family history were unremarkable

On physical examination the patient was of athletic build His blood pressure was 121/98 mm. Hg pulse 76/minute and regular respiration 16/minute and temperature was 98 9 F The jugular pulse showed a prominent a" wave Carotid arterial pulse had a normal upstroke without thrill. There was no heave or thrust of left or right sided ventricular enlarge ment The first heart sound wa normal There was a harsh, grade 4 systolic murmur with a thrill in the second intercostal space The murmur did not vary in intensity with respiration An additional sound was audible in mid-diastole

His chest roentgenogram showed mild cardiomegaly with out specific right ventricular enlargement or poststenotic dilatation of the pulmonary artery The pulmonary vascular pattern appeared normal The ECG revealed normal sinus rhythm and relatively prominent R waves with ST T abnor malities in Leads V and V suggestive of right ventricular strain The phonocardiograms (Figs 1 and 2) confirmed the auscultatory findings and in addition demonstrated an atrial sound (S) of low intensity In the second left intercostal space a dia tolic sound was recorded (arrow in Fig 1) 150 msec. after A

A conventional echocardiogram with transducer directed across the interventricular septum showed a dilated right ventricle (Fig 2) With the transducer angulated posteriorly and superiorly in the optimal direction for visualization of the pulmonary valve a dense mass was seen moving posteriorly with ventricular systole and anteriorly in diastole (T in Figs 3 and 4) Combined echophonocardiography showed that the point of apparent contact of this mass with the anterior wall of the right ventricle coincided with the first vibration of the diastolic sound noted above (Fig 4)

Right heart catheterization showed a mean right atrial pressure of 7 mm Hg right ventricular pressure of 100/10 mm Hg and pulmonary pressure of 15/7 mm Hg The right ventriculogram demonstrated a dilated right ventricle A large well circumscribed lobulated filling defect was noted in the outflow tract of the right ventricle prolapsing partially through the pulmonary valve with each contraction (Fig 5) The tumor was not attached to the pulmonary valve and did not appear to involve the tricuspid valve nor herniate through

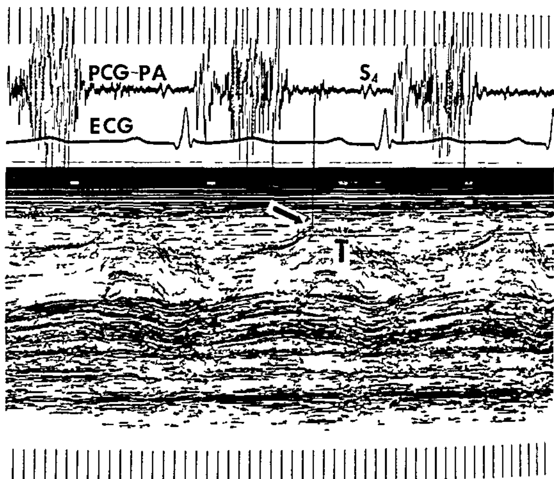

Fig 4 A high speed recording (100 mm./sec) of echophonocardiogram showing the relationship between the tumor motion and diastolic sound In mid-diastole the tumor *(T)* is observed to strike the right ventricular wall *(arrow)* and to induce diastolic vibrations With atrial contraction preceding ventricular ejection the tumor moved posteriorly This probably reflects the reverse pressure gradient across the tumor in presystole as demonstrated by catheterization

Fig 5 Lateral view of cineangiogram demonstrating the mass in the right ventricular outflow tract *(arrow)*

loud [4, 33] An ejection sound was present in six cases [13, 0, 5, 9, 34] However none of the reported cases had pulmonary valvular stenosis An opening snap was heard in one case with obstruction of the tricuspid orifice [33]

The pulmonic component of the second heart sound (P_2) and the diastolic sound or murmur are noteworthy but were not mentioned in detail in most of the reports S_2 in cases with pulmonary obstruction was variable—widely split and accentuated [3] narrowly split or normal [1]

Diastolic murmurs were described in 11 cases There were three cases with tricuspid rumble due to tricuspid obstruction or regurgitation as mentioned before and four with pulmonary regurgitation [7, 1, 28, 34] Two cases with pulmonary regurgitation had a perforated pulmonary valve and in another case surgical replacement of the valve was performed [1]

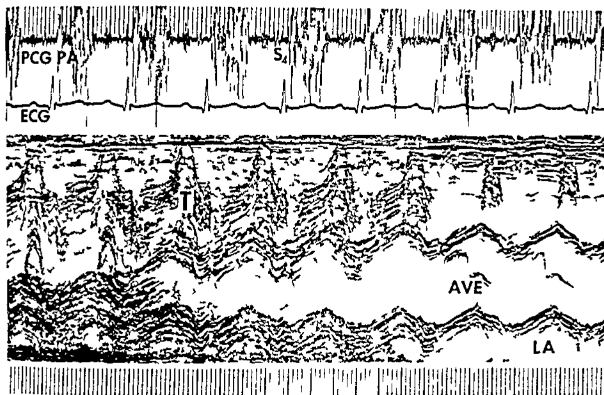

Fig 3 Scanning echocardiogram from the right ventricular outflow tract to the aortic valve *(AVE)* The dense echo of the tumor *(T)* is noted to move forward and backward with each heart beat in the outflow tract *LA* = left atrium

They tend to extend toward the right ventricular outflow tract or even prolapse through the pulmonary valve along with the blood flow in systole Therefore typical cases present clinical findings consistent with pulmonary steno sis—symptoms of dyspnea and syncope with ejec tion systolic murmurs Some cases with atypical findings have however been reported In a rare instance there have been no symptoms In oth ers there have been heart failure without pulmo nary obstruction [2] [33] endocarditis involving the pulmonary valve [16] [28] [34] atrial septal defect [4] pulmonary embolism [2] bronchitis [9] and hemopty sis [1] The duration of symptoms and clinical signs mentioned above varied from five weeks to 14 years [1] There are also familial[16] [24] [3] or recurrent cases [1] [3] reported

In our review of 33 cases there were only two patients without a systolic murmur [2] one of whom had an outflow obstruction gradient of 40 mm Hg [21] Systolic murmurs in the reported cases were initially attributed to pulmonary stenosis and only retrospectively explained by the tumor in 24 cases including three with an associated murmur of secondary tricuspid stenosis [31] or regurgitation [3] The intensity of these murmurs was variable from 2 to 6 the louder ones being associated with a palpable thrill at the upper left sternal border The pressure gradient across the tumor was from 8 to 94 mm Hg and averaged 51 8 mm Hg In one case in which the tumor filled the whole right ventricle to and for scratchy sounds were noted [19] The intensity of the murmur varied with the positional change of the body [1] or from one day to another [4] [13] The effect of respiration on the intensity of the systol ic murmur was inconsistent the murmur being decreased [29] abolished intensified [9] or not changed[13] [22] with inspiration Pan or holosystolic murmurs were present in four cases [8] [9] [1] [3] one of which had an annuloplasty of the tricuspid valve Thus the systolic murmur itself lacked specificity as a diagnostic sign for right ventricu lar myxoma

The first heart sound (S) was unremarkable in all except two patients in whom it was unusually

sents tumor plops It is unknown how often this diastolic vibration occurs in right ventricular myxoma There is a possibility that it is missed or interpreted as delayed P_2 or diastolic murmur unless a phonocardiogram preferably in conjunction with an echocardiogram is carefully recorded We believe its presence would be helpful in making the diagnosis just as with the tumor plop of left atrial myxoma which is due to antegrade movement of the tumor in diastole In conclusion a diastolic sound or short vibration which occurs 130 to 160 msec after A, should be borne in mind as one of the auscultatory findings of right ventricular myxoma in a situation in which pulmonary stenosis is suspected

Summary

Tumors in the right ventricle are extremely rare This report concerns the pathogenesis of physical signs resulting from a right ventricular myxoma In systole a loud midsystolic murmur representing outflow obstruction was present In diastole a prominent vibration was heard and recorded By echophonocardiography this noise could be ascribed to sudden halting of the retrograde excursion of the mass into the right ventricle—a mechanism analogus to the tumor plop associated with the halting of antegrade movement of a left atrial myxoma in the left ventricle in early diastole

Fig 6 Photograph of myxoma exposed by incision of the right ventricular outflow tract

A peculiar diastolic sound resembling that reported by us was described and presented in phonocardiograms of only three cases Sakakibara and associates[13] called this sound which was separated by 130 msec from A and abnormal vibratory phenomenon [13] and Chandraratna and co workers [7] suggested that the sound was a tumor plop rather than P since it was greatly delayed (140 to 160 msec) after A_2 Chandraratna and colleagues observed that the diastolic sound a low pitched thud was coincident with maximum anterior motion of the tumor and with the closure of the pulmonary valve by echophonocardiography Snyder and associates recorded a similar sound and speculated that it might be the delayed closure of the pulmonary valve (150 msec. from A) This explanation was subsequently questioned by Levisman[3] who noted that the sound in question occurred after the v wave of the accompanying jugular venous pulse tracing It should be noted that in these three cases the myxoma had prolapsed through the pulmonary valve just as in our case

Our patient had a sound of short duration in mid-diastole The onset of this vibration coincided with the most anterior position of the tumor in the right ventricular outflow tract by M mode echocardiography This relationship of the impact of the tumor on the right ventricular wall and the appearance of the sound was confirmed from frame-by frame analysis of the tumor movement as determined by angiography We feel that

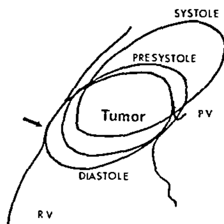

Fig 7 Diagram illustrating the movement of the tumor traced from angiographic frames In mid-diastole the tumor comes in contact with the free wall of the right ventricular outflow tract *(arrow)* With atrial and ventricular contraction the tumor is propelled forward through the pulmonary valve *(PV)* The configuration of the right ventricle *(RV)* and PV is taken from an angiographic frame in mid-diastole at the moment of impact of the tumor on the right ventricular wall

this explanation of the genesis of the sound is more reasonable than ascribing it to a much delayed P_2 The sound occurred 150 msec from A which is beyond even the longest separation of A P in the patients with pulmonary stenosis studied by Leatham and Weitzman [3]

In view of these considerations the diastolic sound in the reports of Sakakibara and associates and Snyder and colleagues probably also repre

Torsades de pointes as a manifestation of mexiletine toxicity

Mexiletine a new antiarrhythmic agent, has recently been released for clinical use Structurally related to lidocaine it belongs to the class of local anesthetic antiarrhythmic agents [1, 2] Unlike lidocaine however mexiletine is active following oral administration and has a plasma half life varying between 8 and 20 hours [2] We report a case of mexiletine toxicity associated with an atypical ventricular tachycardia

Case report

A 59 year old man was sent to our Cardiological Department University of Ferrara on December 28 1979 with a diagnosis of coronary heart disease (CHD) ventricular arrhythmias and gastrointestinal intolerance to quinidine A ventriculography in May 1978 had revealed a septal hypokinesia mild cardiomegaly and a left ventricular end diastolic pressure of 23 mm Hg The left ventricle was abnormal (bulged) by palpation and a 2/6 holosystolic high pitched murmur was heard on the mitral area and at the apex The electrocardiogram (ECG) revealed a normal sinus rhythm at a heart rate (HR) of 70 beats/minute rare unifocal ventricular premature complexes (VPC s) and nonspecific ST T changes The P R interval was 0 17 sec the QRS duration 0 09 sec and the QT interval was 0 46 sec Sitting blood pressure (BP) was 125/80 mm Hg and the patient s weight was 78 5 kilograms A 24 hour dynamic ECG revealed multifocal VPC s (1 230 in 24 hr) couplets and runs and three sustained runs of ventricular tachycardia (Fig 1) Lidocaine was given intravenously at a 1 mg/kg loading dose followed by 2 5 mg/minute and it reduced the number of VPC s by over 85% Neither couplets nor runs were observed during the [illegible] hour therapy and observation period It was then decided to treat this patient with mexiletine 100 mg every 6 hr Since the patient did not present with angina pectoris with the possible exception of perhaps one slight episode during effort every 10 days we decided to treat angina only by sublingual nitroglycerin whenever necessary No other therapy was prescribed The patient was requested to come every 10 days for regular checkups Seven days later the patient came complaining of dizziness occasional palpitations and increasing dyspnea A 8-hour dynamic ECG revealed a very good control of the previous VPC s however a new and severe form of ventricular arrhythmia namely a variant of ventricular arrhythmia (Fig 2) was detected At this time the plasma electrolytes were normal potassium 4 4 mEq/L sodium 143 mEq/L calcium 4.9 mEq/L and magnesium 1 6 mEq/L The physical status was practically unchanged Mexiletine was immediately stopped and two 24 hour dynamic ECG s were obtained The ventricular tachycardia did not recur but the VPC s increased progressively and 18 hours after stopping mexiletine they reached the number and the type that were previously seen The patient was then treated with disopyramide 100 mg every 8 hr and atenolol 50 mg/day Three 24 hour and [illegible] 12 hour dynamic ECG s were obtained at 6- to 15-day intervals With this therapy the number of VPC s decreased by 65% to 76% and the couplets or runs were no longer observed Until the time of writing (February 14 1980) the patient felt relatively well and does not complain of palpitations syncopes or related symptoms Ventricular tachycardia has not been observed

Discussion

This patient s arrhythmia seen during mexiletine treatment represents a variant of ventricular tachycardia and we believe that it fulfill the criteria for the torsades de pointes We could not document the origin of this torsade de pointes by means of electrophysiological studies However we believe that it was of ventricular origin Indeed no P waves were evident The atypical rhythm resembles some of the patient s previous VPC s The patient had also had previous episodes of ventricular tachycardia though more

logically different The PR and QRS intervals immediately before and after this episode of torsades de pointes were within normal limits and the QT did not appear to be pathologically increased Since the plasma electrolytes were within normal limits they cannot be held responsible for this arrhythmia We believe that this torsade de pointes was induced by mexiletine Quinidine [5] disopyramide [6] and also other antiarrhythmics of the local anesthetic type have been found to cause this arrhythmia However quinidine generally induces this arrhythmia in conjunction with a QT prolongation Disopyramide may also prolong the QT interval [4] The rare broadening of the QRS complex induced by mexiletine [2] was not observed in this patient Although we did not obtain plasma levels for mexiletine there were no signs of toxicity Furthermore the patient did not present any signs of renal or hepatic failure It is therefore unlikely that this side effect was secondary to an excessively high dose of mexiletine

Conclusions

Mexiletine is a useful antiarrhythmic agent effective against ventricular arrhythmias asso

ciated with a variety of cardiac diseases Its oral effectiveness its relatively long duration of action and the relatively low incidence of serious side effects indicate that this drug has its place among the antiarrhythmic agents However though rarely mexiletine similar to the other antiarrhythmic drugs of the local anesthetic type may cause the feared torsades de pointes Until now this side effect had not been observed with lidocaine and it was therefore surprising that mexiletine electrophysiologically and chemically similar to lidocaine could indeed induce this arrhythmia

Historical background

The use of electrical energy for reverting diverse cardiac tachyarrhythmias has in the last 20 years become standard practice because of its safety and reliability Contemporary clinical cardiology and cardiac surgery have been significantly affected by the ready availability of a simple method for terminating atrial and ventricular arrhythmias But interest in electricity for medical use is hardly contemporary Preoccupation with galvanic current both for amusement and for resuscitation can be documented in the eighteenth century [1] Possibly the earliest case of successful resuscitation was that of a three year old child who was shocked through the chest by a discharge from a Leyden jar by a Mr Squires of London [2]

The earliest recorded experimental approach to the use of electrical shock for resuscitation was that of Abildgaard[3] in 1775 He shocked hens delivering a sufficient charge to render them lifeless Subsequent shocks revived the birds and he noted that shocks to parts other than the chest were ineffective Abildgaard was unaware of ventricular fibrillation (VF) as this arrhythmia was described only in 1849 by Ludwig and Hoffa Based on extensive physiological studies of the heart McWilliam suggested in 1889 that VF was the mechanism of sudden death a conclusion which is sanctioned by contemporary observations In 1899 Prevost and Battelli [7] while investigating the effects of electricity on animals noted that weak currents induced and strong AC or DC currents terminated VF A reliable method to terminate VF had to await further developments

With the introduction of the dynamo and the development of commercially available electric power a new industrial hazard emerged The first electrocution in the USA occurred in 1879 and this number grew rapidly It soon became apparent that such deaths were due to VF Kouwenhoven and his colleagues[9-] examined both AC and DC circuits for defibrillation and concluded that AC gave superior results They also studied the effects of chest massage which had been commented on previously by Prevost and Battelli in their defibrillation studies Ferris and co workers [1] in 1936 succeeded in closed chest defibrillation in sheep using AC The culmination of these studies came in 1947 when Beck and colleagues defibrillated the exposed human heart at surgery with complete recovery of the patient Closed chest defibrillation in man was first accomplished again using an AC device in 1956 by Zoll and co workers [15]

Up until the early 1960 s AC was thought to be the definitive measure for defibrillation The earlier work of Gurvich and Yuniev[16] in the Soviet Union and of McKay and Leeds[18] in the United States established a basis for the exploration of DC or capacitor discharge Subsequent investigations by Peleska[19-21] outlined the physiologic and pathologic consequences of electrical discharge as well as the circuit characteristics for safe defibrillation Contemporaneous studies by Lown and co workers [4] demonstrated that DC

especially important to record since immediately following reversion the P waves may be diminutive in the limb leads and the rhythm may be irregular The interpretation would then be of continued atrial fibrillation if this is the rhythm being treated and the patient is thereby subjected to unnecessary discharges at higher energies

C Anticoagulation Anticoagulation prior to cardioversion is unnecessary in the patient with the acute onset of atrial fibrillation or if its duration has been less than a week However many patients who are aware that they have experienced a change in rhythm underestimate the time onset of the fibrillation Thus in view of the potential for embolic events within this group of patients we routinely anticoagulate patients for a period of three weeks prior to cardioversion Following cardioversion anticoagulation is maintained for one month Other atrial arrhythmias do not require anticoagulant drugs

Termination of specific arrhythmias

1 *Atrial fibrillation* Prior to the introduction of cardioversion restoration of sinus rhythm was time consuming and hazardous requiring the use of increasing doses of quinidine on successive days This was carried out until the patient became either very ill or until sinus rhythm was restored The procedure frequently required a week or more The initial experience by Lown and co workers [7] from this laboratory detailed results with cardioversion among 50 patients with 65 episodes of atrial fibrillation In this group of patients the arrhythmia was successfully terminated in 58 of 65 or 89% of episodes The results were particularly striking in view of the fact that many of the patients had been in chronic fibrillation over many years that these patients were largely resistant to quinidine reversion and that in a number cardioversion was carried out immediately after mitral valvular operation Energy requirements for reversion are a function of the duration of the rhythm disorder Thus patients with atrial fibrillation in excess of six months required a mean energy of 150 wsec while those with AF of less than three months required 100 wsec The size of fibrillation or 'f' waves in Lead V_1 provides an important clue as to the energy requirement and whether indeed cardioversion will succeed The energy for reversion is inversely related to the size of the 'f' wave Thus when three groups of 50 patients each were segregated as to 'f' wave amplitude those having less than 1 mm amplitude required 140 wsec in those with dimensions of 1 0 to 2 0 mm 116 wsec was effective while in those exceeding 2 0 mm 9? wsec was required [4] It is our practice to titrate energies to 400 wsec if necessary However 9? of patients are usually reverted with 200 wsec or less

When patients are electrically reverted from atrial fibrillation several outcomes are observed A fairly common sequence involves long periods of sinus node asystole with junctional escape followed rapidly by sustained sinus bradycardia with a gradually accelerating rate This has been designated as the somnolent sinus syndrome and reflects recovery of the sinus node from prolonged overdrive suppression by chaotic atrial depolarizations A less common sequence involves an ever changing sinus rate with differing P wave morphologies Bradycardia alternating with variable atrial rhythm and multiple atrial premature beats as well as paroxysms of tachycardia are additional hallmarks of this syndrome which Lown designated the "sick sinus syndrome" [4] Generally such abnormalities in generation and conduction of the sinus impulse are observed following cardioversion of patients with atrial fibrillation of several years duration It frequently augurs the prompt recurrence of atrial fibrillation Among patients with recent onset of atrial fibrillation neither of the above sequences occurs A "strong" sinus rhythm with an unchanging P wave follows within 1 0 to 3 0 seconds after the electrical shock The rate is sustained between 60 to 90 per minute without arrhythmia or interrupted by occasional atrial ectopic beats

Maintenance of sinus rhythm is facilitated by the use of antiarrhythmic drugs specifically quinidine We initiate this agent 24 to 48 hours prior to cardioversion in divided doses totalling 1 2 grams daily Use of quinidine reduces the energy for cardioversion effects a 10% to 15% pharmacologic reversion to sinus rhythm and stabilizes the atrium thereby decreasing the likelihood of post cardioversion recurrence of arrhythmia [4] The prolongation of the QT interval by quinidine is generally without hazard except in a small number of patients who have mitral valvular regurgitation and a high frequency of ventricular premature beats These patients are at a higher risk of

selected for triggering the electric discharge The physiologic basis for cardioversion is that electrical discharge depolarizes part of the reentrant pathway that is non refractory Once an arrhythmia is initiated it may be self sustaining Continuation of the arrhythmia may be due to the existence of a reentering wavefront of excitation traversing a fixed or a variable pathway The advancing wavefront of depolarization is separated from its tail by fully recovered tissue the so-called excitable gap Depolarization of the excitable tissue in the reentry circuit will essentially close the gap preventing sustenance of the arrhythmia That such depolarization of the excitable gap is indeed the basis for the effectiveness of cardioversion is supported by the observation that this technique is equally effective irrespective of where in the cycle the discharge is delivered The above explanation accords with current electrophysiologic understanding It does not explain however why arrhythmias such as fibrillation be they atrial or ventricular require larger energies than those necessary for atrial flutter or ventricular tachycardia

Method of cardioversion

The procedure should be fully explained to the patient to allay anxiety as the amount of energy required is related to the level of agitation and unease Cardioversion should be performed following an overnight fast or omitting the previous meal in more urgent cases Intubation is not necessary If the patient is on a digitalis drug this medication need not be withheld Serum levels of digoxin and electrolytes should be obtained on the day prior to the procedure Prothrombin time is obtained if the patient has been anticoagulated for atrial fibrillation Cardioversion is preferably carried out early in the day in a room equipped for cardiopulmonary resuscitation There should be a minimum of personnel and activity The patient should be warm comfortable and unencumbered by tight fitting clothes An intravenous infusion is started for drug administration Blood pressure is monitored prior to and during administration of the anesthetic Once the procedure is completed the patient is electrocardiographically monitored for one hour before being released

A Anesthesia Initial sedation is provided by administering 100 mg of phenobarbital intramuscularly an hour before the procedure The sedation thus provided reduces the amount of diazepam (Valium) to be given subsequently At the time of cardioversion an initial intravenous dose of 5 mg of diazepam is administered followed by 2 5 mg increments every two to three minutes Both blood pressure and respiratory rate are monitored prior to each dose The average amount of diazepam required to achieve adequate sedation with amnesia in over 500 cardioversions was 15 mg although the range is quite variable and up to 50 mg may be administered without ill effects

B Cardioversion technique The main danger in transthoracic electric discharge is the provocation of VF The current generation of cardioverters incorporates an automatic mode which displays and inscribes the precise location of the capacitor discharge on the R wave The lead which best displays the highest R wave amplitude should be selected for discharge synchronization The risk of provoking ventricular fibrillation in a nonsynchronized discharge is less than 5% Improper synchronization may result when the electrocardiographic signal contains artefactual spikes when there are extremely prominent T waves and in bundle branch block when the R wave is taller than the R wave

Both anteroposterior and anterolateral electrode positions have been employed in cardioversion and defibrillation The anteroposterior position reduces energy requirements by 50% and thus potential complications are reduced [2] [4] The anterior electrode is held firmly along the right sternal border at the level of the second and third intercostal spaces while the posterior electrode is placed at the angle of the left scapula The electrodes must be completely covered with conductive gel particularly along the edges to reduce the likelihood of skin burns

During elective cardioversion energy titration should be employed with an initial setting at 5 wsec Low energies may disclose rhythm disturbance in patients with subclinical digitalis toxicity or electrolyte disturbance and may also reduce myocardial damage The emergence of ventricular arrhythmia in such circumstances requires prompt use of lidocaine The procedure is then continued utilizing increasing energies of 10 25 50 100 200 300 and 400 wsec until reversion occurs After each successive discharge monitoring of Lead II or V_1 will assist in defining the resumption of sinus rhythm The latter lead is

necessity in these cases In many of these patients we deliberately attempt to induce this chronic rhythm disorder as the rhythm of choice

2 Supraventricular tachycardia The majority of supraventricular tachycardias (SVT) do not require cardioversion as they usually respond to vagal maneuvers Vassaux and Lown[5] found that patients coming to cardioversion for SVT had been hospitalized with that arrhythmia for several days and had failed to revert despite the use of a variety of antiarrhythmic agents There has been a reluctance to employ cardioversion for the patient with organic heart disease who experiences SVT In part this is due to the fact that digitalis overdose may be responsible for paroxysmal atrial tachycardia with or without block Cardioversion of such patients may be hazardous Indeed death has been reported following cardioversion in patients with digitalis induced supraventricular mechanisms[3,33] Yet the greatest urgency for reversion to normal rhythm may exist in patients with these very arrhythmias Since these arrhythmias frequently occur in patients with substantial organic heart disease and significant congestive manifestations the rapid ventricular rate encroaches further upon an already compromised ventricular reserve If the mechanism is due to digitalis intoxication cardioversion is contraindicated If however the likelihood of such intoxication is remote cardioversion is the measure of choice Titration of energy permits safe reversion of digitalized patients with SVT

Occasionally clinical circumstances do not clearly define the presence of digitalis toxicity Cardioversion may then be employed as a diagnostic modality The emergence of ventricular ectopic activity or higher degrees of atrioventricular block without reversion to sinus rhythm at low energies strongly suggest digitalis toxicity When ventricular arrhythmias are provoked these are promptly controlled with intravenous lidocaine If after successive discharges the ectopic mechanism is not abolished but ventricular ectopic beats increase in frequency multiformity and repetitive pattern it is likely that overdigitalization is the underlying condition and it is best to desist from further attempts at cardioversion

3 Atrial flutter Prior t[illegible] [illegible] [illegible]dvent of cardioversion, atrial flutter was [illegible] the most difficult arrhythmias to manage Alth[illegible]h the mechanism for this arrhythmia h[illegible] [illegible]een definitely established clinical and experimental evidence indicates that it is the result of a circus movement as defined by Lewis and associates[3] This arrhythmia is often refractory to the conventional antiarrhythmic agents including quinidine procainamide propranolol and disopyramide Large and often toxic doses of digitalis glycosides may be required in order to obtain ventricular rate control and even then difficulty in producing consistent block at the atrioventricular junction results in episodic ultra rapid rates with troublesome palpitation It may be life threatening if 1 1 A V conduction should develop Cardioversion is now the method of choice for terminating atrial flutter Numerous reports have documented that this technique is 72% to 100% effective[4,5,31,3] Lown[4] found that atrial flutter is successfully terminated in 97% of cases The effective energy is generally less than 50 wsec with the average requirement of 25 wsec in over 200 patients studied with this arrhythmia Usually only a single discharge is necessary

When atrial flutter is recurrent notwithstanding the use of antiarrhythmic drugs when the arrhythmia recurs shortly after successful cardioversion, or if cardioversion is unsuccessful in restoring normal sinus rhythm it is our practice to attempt to establish atrial fibrillation as the rhythm of choice This can be accomplished by the use of large doses of digitalis glycosides following which atrial fibrillation may emerge Another therapeutic option is to utilize a low energy discharge during cardioversion The technique is more effective and carries less morbidity Experimental and clinical data have shown that if a stimulus is applied to the vulnerable period of the atrium atrial fibrillation will occur[3] Since flutter is likely to be a reentrant mechanism some parts of the atria are always undergoing depolarization while other parts are in a state of refractoriness or incomplete repolarization Thus the vulnerability to fibrillation is present throughout the flutter cycle and a low energy discharge given at any time in the cardiac cycle stimulating some incompletely recovered atrial tissue will convert atrial flutter to fibrillation About 50% of subjects with atrial flutter who receive such low energy discharges will develop atrial fibrillation if the shock is inadequate to restore sinus rhythm The median shock necessary to induce fibrillation with this method is 1[illegible] wsec with a range of 1 to 20 wsec

experiencing quinidine syncope It may be wise to substitute another antiarrhythmic agent in these cases Maintenance of sinus rhythm beyond 12 months is accomplished in *less than one half* of patients with atrial fibrillation [47] This is particularly true for the patient whose atrial fibrillation is associated with altered left ventricular function

Determination of which patients are suitable for elective cardioversion from atrial fibrillation requires careful assessment of the patient and knowledge of contraindications of the procedure Cardioversion may not succeed or is relatively contraindicated in the following groups of patients with atrial fibrillation

(a) Atrial fibrillation of prolonged duration Higher energies are required for reversion of atrial fibrillation of prolonged duration and the success rate is low We generally limit elective cardioversion to patients who have been in chronic atrial fibrillation for less than one year In those with arrhythmia of longer duration sinus rhythm *is unlikely* to persist in more than *half* the patients [4, 7, 51]

(b) Mitral valvular disease with markedly enlarged left atrium Chronic mitral regurgitation or stenosis alters both the size and mean pressure of the left atrium This provides conditions for a sustained fractionation of reentrant excitability and is particularly the case in those having a giant left atrium secondary to mitral regurgitation Prior to the onset of atrial fibrillation a number of these patients will have exhibited first degree atrioventricular block and frequent atrial premature beats, which are associated with relapse of atrial fibrillation While reversion to sinus rhythm is simple maintenance of a normal mechanism with current antiarrhythmic drugs is often difficult or even impossible

(c) Atrial fibrillation in the setting of left ventricular failure The patient experiencing altered left ventricular *function may* develop acute atrial fibrillation secondary to elevated left sided filling pressures and subsequent atrial distension This may be the clinical setting of a patient with an acute myocardial infarction In this situation the use of digitalis drugs to decrease the ventricular response to atrial fibrillation thus improving ventricular function will usually result in restoration of sinus rhythm Myocardial infarction is however not a contraindication for electrical reversion Cardioversion carried out in the patient with severe pulmonary congestion will probably not restore sinus rhythm especially when atrial fibrillation was not the initiating factor Occasionally a patient with a far advanced cardiomyopathy who is anticoagulated will benefit from the augmentation of cardiac output derived from even a brief period of sinus rhythm Hence the management of this type of patient might include periodic cardioversion

(d) Lone atrial fibrillation Atrial fibrillation is not uncommon in the absence of demonstrable heart disease The left atrial and left ventricular chambers are usually normal in size and fibrillatory waves are diminutive in Lead V_1 Maintenance of sinus rhythm is difficult despite the use of antiarrhythmic agents and cardioversion is of limited application However there exist no prior methods for ascertaining the patient who will sustain sinus rhythm for either long periods or even permanently It is therefore worthwhile to subject such patients to at least one cardioversion

(e) Atrial fibrillation with a slow ventricular response The majority of patients with acute atrial fibrillation exhibit a ventricular response in excess of 130 beats/minute Frequently one encounters an elderly patient not receiving digitalis or beta adrenergic blocking agents whose ventricular response is 70 beats/minute or less The absence of tachycardia most probably reflects the coexistence of atrioventricular conduction disturbance Reversion to sinus rhythm may be associated with extreme bradycardia requiring the use of a permanent pacemaker Atrial fibrillation is far preferable in these cases

(f) Adverse reaction to antiarrhythmic agents Maintenance of sinus rhythm following cardioversion requires the use of chronic antiarrhythmic therapy Thus patients who are unable to tolerate antiarrhythmic drugs such as quinidine or disopyramide or who experience a recurrence of arrhythmia on these drugs may not be candidates for cardioversion

(g) Recurrent atrial tachyarrhythmias Patients with chaotic arrhythmias (Parkinson Papp syndrome) or those with oft recurring atrial tachyarrhythmias flourish once atrial fibrillation becomes established They no longer are disabled by the frequent paroxysms with the onset of atrial fibrillation Thus atrial fibrillation is the preferred rhythm and becomes a therapeutic

chest massage and correction of acid base balance delivery of two or three 400 wsec shocks in rapid sequence as a last resort may be successful

Reversion during pregnancy Pregnancy may be the setting for recurrent atrial arrhythmias which may be resistant to pharmacologic therapy and cardioversion[7] However both elective and emergency reversion have been performed with safety during all three stages of pregnancy[72,77] Schroeder and Harrison[76] reported seven episodes of cardioversion for PAT in one patient during various stages of pregnancy In all attempts 100 wsec terminated the abnormal rhythm Grand and Bernard[77] used 300 wsec to revert atrial fibrillation successfully without disruption of fetal heart rhythm However suspected fetal distress necessitated cesarean section for delivery In other reports[73,75] cardioversion did not induce premature labor Defibrillation during pregnancy presents no real therapeutic dilemma as death of the mother and the fetus will almost certainly supervene otherwise Curry and Quintana[8] reported the successful termination of VF during acute myocardial infarction with a single 300 wsec shock The fetal ECG was unaffected by the discharge but the mother was subsequently found dead presumably as a result of recurrent VF

Fetal rhythm should be monitored during cardioversion Induction of VF by the electrical discharge during the fetal ventricular vulnerable period is remote and the energy reaching the fetal heart is minuscule Furthermore it is known that the hearts of small mammals can be fibrillated only with great difficulty and the disordered rhythm is often self terminating This is presumably because a critical myocardial mass is necessary to sustain VF

Complications

a Morphologic and functional damage A large number of studies demonstrate that electrical discharge causes both morphologic and functional derangements Grossly recognizable as well as microscopic damage may occur[2 3 4 8 8] Lown and colleagues demonstrated progressive changes consistent with the release of tissue potassium as successive high energy shocks were delivered Electrically induced tissue damage is considerably less with DC as compared to AC shocks[23 24 82] Dahl and co workers[83] quantified myocardial damage by precordial mapping and by gross and microscopic pathologic studies in dogs Myocardial damage was greatest when small electrodes were used and when shocks were closely spaced They recommended that during elective cardioversion shocks be spaced at intervals of more than 3 minutes to spare the heart from damage Davis and co workers found that if energy levels less than twice the threshold strength necessary for defibrillation were delivered minimal myocardial damage occurred in dogs Progressively more severe necrosis occurred with increase in delivered energy In a similar study Van Vleet and colleagues[5] concluded that a relatively broad safety margin existed between the threshold energy required for defibrillation and the energy levels which produced significant cardiac damage and death in healthy dogs Warner and co workers found areas of permanent cardiac damage as evidenced by scarring and calcification following repeated shocks lesions were characteristically subepicardial

Following electrical shock there is release of myocardial creatine phosphokinase (MB CPK) as well as other enzymes In man myocardial damage has been examined during elective cardioversion[84] None of 27 patients who received less than 425 wsec either in single or cumulative shocks demonstrated a rise in MB CPK In two of three patients who received a cumulative delivered energy dose of more than 425 wsec MB CPK was elevated Myocardial scintigraphic studies likewise confirm that the extent of damage in dogs subjected to shocks was proportional to the quantity of energy delivered to the heart[8] It is clear from the numerous studies cited that myocardial damage certainly occurs especially with repeated high energy shocks The use of high energies with inadequate skin preparation also leads to painful skin burns Impeccable technique with proper electrode positions and adequate conductive paste should therefore be used at all times

In addition to morphologic damage functional derangements result from electric shocks Fi... kin[81] noted intracardiac temperatures as high as 47° C after shocks to the exposed heart Depression in left ventricular function and contractility may result[4 81] Koning and colleagues[1] showed in isolated perfused hearts decreases in dp dt and an increase in diastolic stiffness and left ventricular diastolic pressure following electric shocks

4 Ventricular tachycardia Ventricular tachycardia (VT) may be due to an ectopic focus or to a reentrant mechanism Enchanced automaticity is the basis for ventricular tachycardia resulting from digitalis intoxication or during the initial period following acute myocardial infarction However the most frequent mechanism is reentry This suggests that cardioversion may be useful for terminating a majority of these episodes Since the first reported case of ventricular tachycardia reverted with AC shock electrical discharge has become the standard and routinely employed therapeutic measure Cardioversion should be used expeditiously in the critically ill patient with ventricular tachycardia associated with hypotension pulmonary edema or an acute myocardial infarction when intravenous lidocaine has failed The reported success rate varies from 95% to 100% [3, 5, 59] The energy requirements are almost always less than 100 wsec As little as 1 wsec will convert some cases of ventricular tachycardia and in 80% of cases 10 wsec or less has proved adequate [6]

When ventricular tachycardia is rapid and the QRS complex is wide and bizarre in configuration a broad prominent T wave may not be distinguished from the QRS complex The disorder has been termed ventricular flutter of VT of the vulnerable period (VT) Cardioversion affords a 50% chance that the discharge will occur at the apex of the T wave instead of during inscription of the R wave In fact instead of avoiding the vulnerable period the shock is synchronized to fall precisely during its midst When confronting such a problem it is advisable to switch to the defibrillator mode and deliver a nonsynchronized shock of 100 wsec this practice diminishes the likelihood of provoking ventricular fibrillation

5 Ventricular fibrillation The vast majority of cardiac arrests are due to VF [41] Defibrillation constitutes definitive treatment for this condition and success is assured only if prompt defibrillation is accomplished Although the ideal electrode positions are not known in man it is reasonable to assume that they will approximate those for elective cardioversion of atrial and ventricular arrhythmias

Initial defibrillation in adults should be conducted with a setting between 300 to 400 wsec Lower energy settings with rapid sequential discharge as practiced by some workers [2] should preferably be employed only if the resuscitation team is highly experienced Valuable time may otherwise be lost due to inefficient or improper application of the procedure Some newer defibrillators may have energy settings in excess of 400 wsec Such devices should be used with care as the possibility of serious cardiac damage and complications is increased The initial setting should never exceed 400 wsec At present there is no evidence that energies in excess of 400 wsec are ever needed in man for defibrillation If higher energies are used prolonged periods of asystole or complete heart block may ensue resulting in resumption of VF Repeated shocks with high energy result in resumption of VF due to progressive myocardial deterioration ultimately rendering termination of VF impossible

Clearly the above recommendations are excessive for pediatric subjects Gutgesell and colleagues in studying 27 children weighing between 2 1 to 50 kilograms terminated 63 of 71 episodes of VF with shocks up to 300 wsec A setting of 2 wsec/Kg ± 10 wsec was used for most of the episodes and 91% of shocks in this range were successful in terminating VF Five of the eight failures in this series of patients occurred with the recommended energy level two occurred at lower settings and one at a higher setting The authors caution that refibrillation is not an indication to increase the energy dose At the present time there are inadequate data to make definitive recommendations for pediatric defibrillation However experience to date indicates that repeated high energy shocks are inappropriate especially for small children Defibrillation of the heart during open chest surgery is another setting where low energy shocks are used In most situations shocks of 5 to 10 wsec are adequate

Ventricular fibrillation of prolonged duration may be resistant to electric shock regardless of the amount of energy used In this situation repeated high energy shocks produce momentary asystole with resumption of fine-grain VF Such a situation requires correction of acid base imbalance and hypoxia before further attempts are made Administration of a beta adrenergic agonist such as epinephrine or isoproterenol may convert a fine-grain pattern to coarse grain VF The latter variety of VF is more susceptible to electrical termination If repeated single shocks fail to terminate VF despite adequate ventilation

following cardioversion had mitral or aortic valvular disease or left ventricular dysfunction Increase in cardiac output with return of atrial systole following cardioversion[106, 108] and concomitant depression in left ventricular function by electric shocks may be contributing factors to the development of heart failure Occasionally return of left atrial systole is delayed after cardioversion so that the disparity in outputs of the right and left sides of the heart may be expected[91, 10, 111] This may lead to an increased volume load on the left ventricle resulting in pulmonary edema

e Embolism Approximately 30% of patients with atrial fibrillation may experience spontaneous serious embolic episodes during their life time[11] The risk of embolism is increased immediately following both pharmacologic or electrical reversion to sinus rhythm In 400 patients reverted with quinidine Goldman[113] encountered an incidence of 1 5% Pulmonary as well as systemic embolization may also follow cardioversion[4, 1, 9, 111, 11] The majority of patients experiencing this complication were not receiving anticoagulants prior to cardioversion The incidence of embolism in 450 episodes of atrial fibrillation treated with cardioversion was approximately the same as following reversion with quinidine at 1 2%[4] None of 100 patients on anticoagulants experienced embolism as a complication Postponed resumption of atrial systole may account for the delayed embolism occurring several days to a week after cardioversion Ikram, Nixon and Arcan[1,9] demonstrated delayed return of left atrial activity for 3 to 6 days and in one case no atrial activity was detected for 6 weeks following cardioversion Absence of mechanical activity in left right or both atria has been commented on by other workers as well[94, 11, 111] Thus anticoagulation should be performed not only 3 weeks before but also for at least 1 week following cardioversion

f Miscellaneous complications Resnekov and McDonald noted hypotension following cardioversion in 3? of 220 patients Decrease in blood pressure is usually transient but may last several hours and generally requires no treatment Transient cardiac enzyme elevation and ST segment and T wave changes not necessarily related to significant myocardial damage may also occur[4, 93, 9] There is little information on the effects of electric shock in producing failure of implanted artificial pacemakers[11, 111] However this complication has been rarely encountered and therefore should not impede cardioversion

Damage to adjoining as well as remote structures has been reported as a consequence of the electrical discharge Pericarditis[1] ocular damage,[11] transient left recurrent laryngeal nerve paralysis[120] and vertebral fracture[1] have been described Some of these complications are due to the physical trauma resulting from body movement following high electrical energy discharge

Controversies in defibrillation

a Energy dose for defibrillation Tacker Geddes and their co workers[12, 125] have indicated that conventional devices storing 300 to 400 wsec are inadequate to defibrillate adults weighing over 70 kilograms Geddes and associates found that in animals the threshold energy for defibrillation increased with body weight Tacker and colleagues[1] reported on a series of 111 patients in whom defibrillation success ostensibly declined with increase in body weight They derived a dose response curve based on 13 subjects and concluded that a third of patients weighing over 70 kilograms could not be defibrillated They recommended a dose of 3 5 to 6 wsec/kg for successful defibrillation This opinion is not persuasive and the evidence countering it has been presented elsewhere[1, 6] The data of Tacker and associates[1, 3] and of Collins and colleagues,[1] the latter being merely an expansion of the former study were collected retrospectively and provided no information on electrode position, duration of fibrillation underlying heart disease or estimates of delivered energy Furthermore statistical analysis of the data they provide does not support their claim that heavier patients were more difficult to defibrillate In contrast to these data Kerber and Sarnat[1] showed in their detailed retrospective study that defibrillation success bore no relation to body weight On the contrary their data suggested that use of high energies was associated with decreased survival

Numerous studies show that heavy patients can indeed be defibrillated using conventional devices storing 400 wsec Several case reports[78, 12, 11] attest to the successful reversion of VF in heavy patients Prospective studies on VF by Pantridge and co workers[4] and by Crampton and associates[4] and using devices sto…

Release of potassium CPK acetylcholine and catecholamines following shocks may also occur[1] Regan and associates[9] found high levels of potassium in coronary sinus blood following transthoracic shocks to the digitalized heart The quantity of potassium released was proportional to the electrical energy delivered to the heart and they concluded that potassium release by electric shock was enhanced in the presence of digitalis glycosides

b **Cardiac arrhythmias** Peleska showed that the energy content of the shock was related to both the extent of morphologic damage as well as the severity of ventricular arrhythmia Lown and co workers[70] noted in dogs that 3% exhibited ventricular tachycardia after a single 100 wsec shock while 25% showed this arrhythmia after 200 wsec and 65% after 400 wsec Subsequent studies confirmed that ventricular arrhythmias could be evoked following defibrillation or cardioversion[51 54] In man a variety of arrhythmias have been described ranging from ventricular premature beats, bigeminy salvos of mul focal beats ventricular tachycardia and brillation These arrhythmias need not be a onsequence of myocardial damage alone When F occurs during cardioversion it is usually due) improper synchronization However a number f reports document the emergence of VF some mes leading to death several minutes or even ours after the shock[5 7] These patients had een receiving quinidine digitalis glycosides or oth at the time of onset of VF and these drugs ave been implicated in provoking this arrhyth nia[55 97]

Digitalis intoxication in particular greatly ensitizes the heart to electrical dis harge[2 30 31 56 89] In dogs an eight thousandfold ncrease in sensitivity to electric shock occurred ollowing administration of a toxic dose of ouabain as judged by the emergence of repetitive ventricular activity[30] It required 60% to 80% of the toxic dose of ouabain to demonstrate such sensitization In man Kleiger and Lown[7] found that 18 of 100 digitalized patients undergoing cardioversion showed frequent ventricular pre mature beats bigeminy or ventricular tachycardia In comparing these 18 patients with the remaining 82 the pre cardioversion electrocardiograms of the former group showed more frequently arrhythmias suggestive of digitalis toxicity These arrhythmias included ventricular premature beats junctional rhythm with or without atrioventricular dissociation and first degree heart block Two patients also had episodes of atrial tachycardia with block Patients in atrial fibrillation with ventricular rates of less than 70 per minute and episodic regularization of rhythm had an almost 50% risk of developing ventricular arrhythmias following cardioversion The grade of arrhythmia increased as a function of the discharged energy

The patients who developed VF and died as reported by Rabbino and colleagues[33] and by Ross[4] had also received high doses of electrical energy in the presence of digitalis toxicity This experience underscores the extremely hazardous nature of high discharge energies in overdigitalized patients The mechanism whereby digitalis sensitizes the myocardium to electrical shock is not clear Lown Black and Moore[100] hypothesized that electrical shock alters cation transport across cell membranes promoting efflux of cellular potassium Such losses are enhanced in the excessively digitalized heart thus promoting the emergence of life threatening ventricular arrhythmia The studies by Regan and colleagues on dogs digitalized with acetyl strophanthidin and shocked electrically provide experimental support for this hypothesis Although quinidine facilitates reversion in atrial fibrillation pretreatment with quinidine prior to cardioversion clinically has not been shown definitively to be protective against the development of subsequent ventricular arrhythmias

Electrical discharge can induce relatively more benign arrhythmias such as atrial ectopic beats and impaired atrioventricular conduction Complete heart block following cardioversion or defibrillation may also occur and its duration is a function of the amount of energy delivered Use of energies of the order of 300 to 400 wsec however may result in prolonged periods of heart block or asystole which favor the reemergence of ventricular arrhythmias including fibrillation

d **Pulmonary edema** Resnekov and McDonald[1] reported on the occurrence of pulmonary edema in four patients within 24 hours of cardioversion Subsequent studies have confirmed this finding[95 6 103 105] Among 750 patients we have seen three patients with pulmonary edema and these had pulmonary embolism It is uncertain if additional mechanisms are involved The majority of patients reported with pulmonary edema

Subsequently a single catheter system with two sets of electrodes on the same catheter has been developed The sensing unit consists of either a pressure transducer or a contraction sensor element as an integral part of the catheter The capacitor charges itself if there is absence of detectable pressure or right ventricular contraction and discharge occurs after a preset interval if either of these two conditions persists Preliminary studies show that the method is effective in defibrillating both animal and human hearts using energies from 4 to 35 wsec

Intriguing though the concept is Lown and Axelrod[11] have questioned the merit of implanted defibrillators They point out that malfunction may result if the sensing element should become encased in fibrotic tissue or if the catheter migrates into the pericardial sac Unnecessary and possibly lethal shocks may then be delivered Even if these problems are overcome the question of periodic evaluation for adequacy of performance remains Unlike pacemakers which can easily be functionally assessed implanted defibrillators cannot be so evaluated Verification of adequacy would include not only ascertaining activation of the device exclusively by VF but delivery of a charge sufficient to defibrillate the heart For the present more conventional approaches to the problem of sudden death from VF are preferable

Summary

The use of electrical energy for the immediate treatment of atrial and ventricular arrhythmias is practical and easily applied The method though simple is the most effective method for terminating cardiac arrhythmias and is associated with only a low risk if properly employed In symptomatic patients the utilization of cardioversion reduces patient discomfort and complications which may occur while awaiting pharmacologic reversion of arrhythmia At present transthoracic defibrillation is the only practical method for terminating VF Despite the safety of electrical reversion proper precautions are necessary to prevent complications In particular the discharge of excessive energies especially in the presence of digitalis toxicity promises grave and life threatening consequences The use of antiarrhythmic medications is not supplanted by cardioversion and defibrillation Rather ongoing drug therapy is frequently necessary to prevent recurrence of arrhythmia

400 wsec or less reverted over 95% of patients with VF These workers used either single or multiple or low energy shocks and the mean energy required for defibrillation was frequently 50% less than that recommended by Tacker and colleagues[1,1] When shocks of 200 or 300 wsec failed 400 wsec almost invariably succeeded Crampton and his group[6] found that a mean energy of 194 wsec terminated 45 of 46 episodes of VF in 11 of 12 heavy patients The patients weighed between 91 and 225 kilograms and the mean energy requirement was 1 8 wsec/kg Conventional devices storing 400 wsec thus appear to be adequate for clinical use Delivery of higher energies while likely to induce injury has yet to be shown to be necessary[1,6,130,3]

b Blind defibrillation Grace and co workers[1] have suggested that when encountering cardiac arrest immediate discharge of 200 to 400 wsec be performed in the absence of electrocardiographic confirmation of VF They argue that since VF is implicated in the vast majority of patients having an arrest prompt defibrillation provides the greatest chance for full recovery Although a controlled study was not performed they noted an increase in survival rates from 27% to 45% after blind defibrillation was started in their institution

If cardiac arrest has been presumed to exist by virtue of loss of consciousness and absence of a pulse the mechanism may be VF asystole or electromechanical dissociation The majority of patients however have been found to be in VF Prompt defibrillation will constitute definitive therapy with a minimum of delay A possible hazard exists in a very small minority of patients that they may be shocked during the ventricular vulnerable period while in rhythms other than VF If the mechanism is ventricular tachycardia use of high energies (300 to 400 wsec) will terminate the disorder rather than provoke VF This is due to the fact that a high energy discharge uniformly depolarizes the entire myocardium even if discharged during the vulnerable period Blind defibrillation with such energies is thus an acceptable risk. Electromechanical dissociation during a cardiac arrest usually signifies an unfavorable outcome In such an event it is unlikely that blind defibrillation will exert a deleterious effect on survival The uncertainty regarding the underlying rhythm disorder is resolved if the defibrillator electrodes also function as electrocardiographic monitoring leads providing confirmation of the rhythm immediately before discharge

c Chest thump Pennington Taylor and Lown[..] recommended thumpversion for malignant ventricular tachycardia They found that a precordial blow reverted 12 episodes of ventricular tachycardia in five patients in three of whom myocardial infarction was the basis for the arrhythmia The electrophysiologic basis for thumpversion is unknown However certain observations made during cardioversion suggest an explanation[5] The prefibrillatory arrhythmia designated ventricular tachycardia of the vulnerable period i e VT can be terminated with less than 1 wsec[4] Energies less than 10 wsec will terminate over 90% of episodes of VT[3] Since the small amount of energy delivered by a precordial blow is frequently sufficient to depolarize enough myocardium and initiate a propagated response by electromechanical transduction during cardiac arrest due to asystole[134] it is likely that during VT depolarization by such a blow may be adequate to interrupt a reentrant pathway and thus terminate VT Undue delay however may result in degeneration of VT to VF The steep rise in energy requirement for termination of VF then renders chest thumping ineffective

An objection to this method of reversion has been raised namely that a thump delivered during the ventricular vulnerable period may result in VF The possibility of this event occurring is less than 5% In the hospital the ready availability of a defibrillator should enable electrical termination of VF If the patient has lost consciousness cardiopulmonary resuscitation will be initiated in any case so that an immediate chest thump may be beneficial if the underlying arrhythmia is asystole or VT However the present recommendation of the American Heart Association is that chest thump be reserved for monitored patients only

d Implanted defibrillators In recent years a number of workers have demonstrated that defibrillation through an intracardiac catheter system is feasible[..] The system consists of an intracavitary right ventricular catheter containing one electrode at its tip and another in the superior vena cava alternatively a precordial subcutaneous plate may serve as the other electrode

Rickettsial vasculitis

David H Walker M D *
William D Mattern M D **
Chapel Hill N C

Important rickettsial diseases of man are distributed over all the continents with the exception of Antarctica In order to approach these diseases their etiologic agents must be defined taxonomically Definition of the term rickettsia varies from a nearly meaningless inclusiveness of almost any intracellular microorganism to a narrower consideration of only the genus *Rickettsia* In this discussion the other related genera *Coxiella* (Q fever) and *Rochalimaea* (trench fever) will be excluded Members of genus *Rickettsia* share the following characteristics gram negative bacterial ultrastructural morphology obligate intracellular parasitism ecologic niche including all or a portion of life spent in an arthropod host and serologic grouping relationships There are three serologic groups typhus group spotted fever group and scrub typhus group The concept that rickettsiae are an intermediate form of life between viruses and bacteria is completely outmoded That they are clearly a specialized group of bacteria is confirmed by method of replication (binary fission) content of both RNA and DNA ultrastructural morphology and sensitivity to antimicrobial agents Although rickettsiae are capable of penetrating and growing within a wide variety of host cells of various species and organ sources in man they are found only in vascular endothelium and in some diseases vascular smooth muscle This anatomic distribution determines the basically similar pathology (vasculitis) and pathophysiology (increased vascular permeability) of the rickettsial diseases

Geographic distribution of rickettsial diseases reflects the distribution of infected arthropod hosts and their contact with man Rickettsial diseases of man their etiologic agents vectors and geographic distribution are presented in Table I

Although other rickettsiae have been discovered in various econiches in the United States at this time only *Rickettsia rickettsii* (Rocky Mountain spotted fever) *Rickettsia mooseri* (murine typhus) *Rickettsia prowazeki* (recrudescent typhus) and *Rickettsia akari* (rickettsialpox) have been documented as etiologic agents of disease in man in recent times Evidence indicates that epidemic typhus has probably been transmitted to man from a natural zoonotic cycle of *Rickettsia prowazeki* in flying squirrels in the southeastern states and that *Rickettsia canada* possibly causes a disease similar to Rocky Mountain spotted fever [1] However in current reports Rocky Mountain spotted fever (RMSF) accounts for more than 90% of rickettsial disease with murine typhus a distant second in incidence and the others apparently quite rare [1]

The incidence of RMSF has risen to a high level with continued significant mortality In 19[illegible] only 199 cases were reported and by 1968 the annual total was still only 298 cases Since that time a remarkable increase has occurred peaking at a total of 1 153 cases in 1977 [2] Expressed as rates this is a rise from 0 11 cases per 100 000 population in 1959 to 0 50 cases per 100 000 nationally and 1 66 cases per 100 000 in the South Atlantic states in 1977 Although the mortality rate has fallen from 20% in the preantibiotic era it has remained in the 5 to 10% range to the present time despite the efficacy of tetracycline and chloramphenicol RMSF has been reported from

macules which are from less than one to five *millimeters in diameter blanch completely and* temporarily on pressure and are rarely tender Subsequently these lesions acquire a deep red to purple hue and increase in size even becoming confluent in some cases After 2 to 3 days from its onset the rash becomes nonblanchable and pete chial In severe cases during the third week necrosis of dependent peripheral parts including scrotum, prepuce, fingers toes and external ear may occur

Study of the pathologic lesions in rickettsial disease has been performed most comprehensive ly in epidemic louse borne typhus Wolbach who already had extensive experience in investigating RMSF was sent to Poland with the Typhus Research Commission during World War I His descriptions based on the study of skin from 36 necropsies and skin biopsies from 28 patients covered the range from the first day of rash to the twenty fourth day of disease [14] At the onset of rash (day 3 of disease) the only pathologic lesion was swelling of the endothelium of capillaries and small arteries and veins of the papillary and reticular dermis Rickettsiae were observed in swollen endothelial cells On day 5 of the disease arterioles and venules demonstrated mural thrombi overlying swollen endothelial cells which frequently contained numerous rickettsiae Peri vascular reaction was minimal Subsequently contiguous spread of rickettsiae with accumula tion of increased quantity of organisms was observed in serial sections, moreover the patho logic lesions involved larger vessels in the deep dermis and subcutaneous tissue and included more prominent perivascular mononuclear in flammation Dermal hemorrhages were observed around capillaries and vessels of pre capillary size on and after the eighth day of illness Organization of vascular thrombi was seen as early as the fifteenth day Areas of gangrene were demonstrated microscopically not to be accom panied by thrombosis of large vessels but to be due to thrombosis of capillaries and small arteries and veins beginning in the dermis and extending centripetally

Comparison of the lesions of typhus and RMSF is most remarkable for their similarity However differences which comprise more extensive de struction of the vascular wall including the media and less pronounced perivascular inflammation in RMSF reflect in ction of vascular smooth muscle by *Rickettsia rickettsii* and not *Rickettsia prowazeki* and the generally shorter course of fatal cases of RMSF

Rarely in any disease are the pathologic lesions correlated so closely with the clinical picture A careful study of the patient s clinical record will reveal a very close correlation between the microscopic findings and the physiologic dis turbances although the latter may be out of all proportion to the visible anatomic lesions." These comments by Harell in his review of RMSF in 1949 certainly apply to the physiologic distur bances in the peripheral circulation in the most severe rickettsial infections such as epidemic typhus scrub typhus and RMSF In 1944 Har rell referring to RMSF [15] and Woodward refer ring to epidemic typhus [16] postulated in separate publications that hypotension and circulatory collapse seen at the height of these rickettsial infections resulted not from cardiac weakness, but from peripheral circulatory failure the latter resulting from a decrease in blood volume as a consequence of an increase in systemic capillary permeability They both noted that the falling blood pressure at the height of the illness coin cided with the appearance of edema and with a fall in the concentration of serum proteins, partic ularly albumin

In a more detailed investigation of the patho physiology of the peripheral circulatory failure in RMSF, Harrell in 1949 reported serial observa tions in 13 patients [17] The entire natural history of the illness was observed since neither tetracy cline nor chloramphenicol was then available as specific treatment Sequential measurements of plasma volume (using Evans Blue dye) extra vascular volume (using thiocyanate space) and the serum concentrations of total protein albu min nonprotein nitrogen (NPN) and chloride were correlated with various clinical observa tions and the effect of intravenous therapy with crystalloid and colloid containing solutions was noted The illness was considered mild if the tourniquet test was negative there was no edema and the pulse and blood pressure were stable moderate if the tourniquet test was positive there was slight edema the pulse rate was increased and the patient appeared toxic and severe if there were purpura marked edema and delirium Cases with a fulminant clinical course were not included Data were summarized for the moder ate to severe cases at three stages (1) soon after

Table I

Disease	Etiology	Vector	Geographic distribution
Typhus group			
Epidemic typhus	*R prowazeki*	Louse	Historic all continents except Australia Recent Burundi, Rwanda Uganda Ethiopia Algeria Chad Niger Zambia Nigeria Zaire Liberia Bolivia Peru Ecuador Chile Guatemala Costa Rica Mexico
		Ectoparasite of flying squirrels	Southeastern U S
Recrudescent typhus	*R prowazeki*	None	Worldwide especially localities of previous typhus epidemics, eg Poland and Yugoslavia or countries of immigration of previous typhus cases eg U S and Canada
Murine typhus	*R mooseri*	Rat flea	Worldwide especially in warmer climates including U S
Spotted Fever group			
Rocky Mountain spotted fever	*R rickettsii*	Tick	U S especially southeastern states western Canada Brazil Colombia Mexico Panama
Old world tick borne spotted fever (Boutonneuse fever South African tick bite fever Kenya typhus etc)	*R conori*	Tick	Mediterranean basin Africa Asia
Siberian tick typhus	*R sibirica*	Tick	Siberia
Queensland tick typhus	*R australia*	Tick	Australia
Rickettsialpox	*R akari*	Mite	Probably worldwide documented in cities of U S and U S S R
Central European tick typhus	*R slovaca*	Tick	Central Europe Armenia
Scrub Typhus group			
Scrub typhus	*R tsutsugamushi*	Mite	Eastern and southern Asia and southwestern Pacific

states however there is a higher incidence in the southeastern states with North Carolina Virginia Tennessee Oklahoma South Carolina Georgia and Maryland reporting 66 1% of all cases between 1975 and 1977 Cases occur most often in children in males and between mid April and mid September Moreover mortality rates are higher for adults (over age 30 13 9% vs 5 4% under age 30) males (8 2% vs 4 5% in females) and nonwhites (13 9% vs 5 8% in whites)[6] Fatal cases seek medical attention at the same time during the course of illness as nonfatal cases However their rash appears later they give a history of tick bite less often or later in the course and initial or unexpected symptoms lead to misdiagnosis As a result of incorrect or delayed diagnosis antirickettsial treatment is not given or is given too late to be effective[7]

Effect of rickettsiae on the microcirculation

Dermal involvement in rickettsial diseases is not only a prominent clinical sign but also an opportunity to observe and evaluate the nature of the vascular events The observations indicate that the microcirculation is the primary target with variable subsequent contiguous centripetal extension to arteries and veins The temporal sequence of events which may be seen in the skin of patients with typhus and RMSF reflects the pathologic and pathophysiologic events in these diseases

The rash of RMSF is delayed usually occurring three days after onset of fever with a range of 2 to 7 days and rarely not appearing at all[8, 12] The rash tends to appear first on ankles feet wrists and hands and to spread centripetally to involve the entire body within 24 to 36 hours usually including the palms and soles This centripetal spread contrasts with the centrifugal spread of the rash of typhus The difference has never been satisfactorily explained although optimal growth of *Rickettsia rickettsii* at lower temperatures[13] would favor earlier attainment of a critical mass of pathogenic organisms in peripheral sites. Initially, the rash consists of pink unelevated

strated in the only case of fulminant RMSF with description of pathology reported in the literature.[2] In our case study of serial sections stained for fibrin histochemically and for *Rickettsia rickettsii* immunohistochemically demonstrated that thrombotic glomeruli were intensely infected and that nonthrombotic glomeruli were minimally or mildly infected. In an intermediate position, several recent cases with death occurring on day 6 or 7 of disease have had rare focal glomerular thrombi. These observations on thrombosis in renal tissue from rickettsial diseases indicate that thrombosis is the response to local injury to blood vessels by rickettsiae.

Two lesions which could be due to local and/or systemic effect of rickettsial infections are glomerulonephritis and edema of the kidneys. There is no consensus that glomerulonephritis actually occurs in rickettsial diseases. Glomerulonephritis was described by Allen and Spitz[23] in scrub typhus and RMSF. Ultrastructural examination of renal biopsies from five Brazilian cases of RMSF with various degrees of acute renal functional impairment demonstrated no glomerulonephritis with only nonspecific endothelial swelling and prominence of mesangial cells.[24] Our cases when studied by sections with controlled thickness (3 μm) and staining of basement membranes revealed no glomerulonephritis as judged by the absence of glomerular hypercellularity and basement membrane lesions. Another recent study[25] has shown no glomerular immune complexes by immunofluorescence and no ultrastructural deposits. On the other hand, increased renal weights, presumably secondary to edema, have been reported in some cases of scrub typhus[6] and RMSF.[1] This edema may result from multifocal vasculitis and/or acute tubular necrosis.

The significant pathologic lesion which is the effect of systemic shock on the kidneys is acute tubular necrosis (ATN). In two of 37 cases of typhus fever, heavy kidneys with pale, bulging cortices were compatible grossly with ATN.[11] Although ATN is not always identifiable morphologically in all of its time course and autolysis often renders tubular epithelium impossible to evaluate microscopically, the stage of ATN identifiable by markedly thin tubular epithelium and interstitial edema has been observed in cases of RMSF.[20, 23]

Renal pathophysiology in rickettsial diseases. With reference to [illegible] abnormalities of renal function, the remote effects of the systemic vasculitis far outweigh the effects of the observed intrarenal pathology and can best be understood as the sequential manifestations of altered systemic capillary permeability.[9] Interestingly, the basic renal lesion, a focal perivascular interstitial nephritis, finds little clinical expression. Early in the course of the more severe rickettsial infections, patients often present with dehydration, a moderately elevated BUN and serum creatinine concentration, mild hyponatremia and hypoproteinemia, a low normal blood pressure, and progressive hypovolemia. The BUN is often high in relation to the serum creatinine concentration, and the urine volume is reduced, though usually not to oliguric levels. There is a trace to 1+ proteinuria by reagent stick, and 24 hour collections contain less than 500 mg of protein. The urine sediment contains a few coarsely granular casts but no increase in cellular elements. The urine specific gravity is usually greater than 1.0[illegible] and urine sodium concentration is low, often less than 10 mEq/L. Expansion of intravascular volume with colloid or crystalloid solutions restores renal function to normal within a few days. This entire picture is consistent with prerenal azotemia.

At the height of illness in severe cases with a more protracted course, acute hypotension may precipitate oliguric acute renal failure (ATN). Despite prompt restoration of blood pressure to normal and maintenance of intravasular volume, the oliguria persists. The urine composition and sediment are typical of ATN. Recovery [illegible] ATN, in this setting has been reported in boutonneuse fever, a milder but related rickettsial infection,[27] but not to date in Rocky Mountain spotted fever, although the potential for recovery has been demonstrated. Oliguric acute renal failure is a regular occurrence in fulminant cases, in association with systemic circulatory collapse. Causes other than hypotension have been considered in the pathogenesis of ATN in Rocky [illegible] spotted fever, specifically non traumatic rhabdomyolysis with myoglobinuria, but evidence to support their occurrence is lacking.

As noted, histologic lesions of acute diffuse glomerulonephritis were described in one early report of RMSF. A review of published cases and our own material, however, does not reveal o[illegible] documentation of this lesion, and there is no clinical data (heavy proteinuria, hematuria

onset of the rash (2) at the height of illness 9 to 14 days after onset of the rash and (3) during the recovery period in the third week after onset of the rash

Patients presented shortly after the appearance of the rash with clinical signs of dehydration an elevated NPN and low serum chloride concentration a normal or slightly low serum protein concentration and plasma volume a normal thiocyanate space and a low normal blood pressure When intravenous therapy with crystalloid solutions was given in an effort to correct the dehydration at this point in the illness there was a prompt fall in the NPN and a rise in serum chloride concentration Plasma volume rose transiently and there was a reciprocal fall in the serum protein concentration If crystalloid solutions were continued the expansion of plasma volume was sustained and there was a striking rise in the thiocyanate space coinciding with the development of progressive peripheral edema

At the height of the illness the onset of hypotension was associated with a more marked reduction in the serum protein concentration and plasma volume elevated thiocyanate space and peripheral edema Crystalloid administration at this point accelerated the extravascular accumulation of fluid without a favorable effect on the blood pressure or plasma volume

The onset of recovery was marked by return of temperature to normal and a reversal of the above abnormalities The blood pressure rose to normal as plasma volume began to increase The thiocyanate space gradually decreased as edema was mobilized and diuresed and finally the serum protein concentration returned to normal The administration of colloid solutions such as plasma or albumin in contrast to crystalloids did support the blood pressure and plasma volume at the height of illness and early in the recovery period but in five of the six instances reported its administration also precipitated acute pulmonary edema These findings were interpreted to indicate that the vasculitis of RMSF led to a progressive increase in systemic capillary permeability such that there was a gradual loss of protein from the vascular compartment and a decrease in intravascular oncotic pressure Although this study served to characterize the sequential changes in systemic capillary permeability in the more severe cases it left unanswered important questions about fluid therapy and also raised basic questions about cardiac function and pulmonary capillary function in RMSF

Renal pathology in rickettsial diseases The pathologic lesions of kidneys in rickettsial diseases may be considered to be either of two types lesions due to local effects of rickettsiae on renal vessels or lesions due to the effects of systemic hypovolemic shock In studies of typhus fever Wolbach described focal lesions in which only small blood vessels are affected and the cellular response is infiltrative These lesions contained capillaries or precapillary blood vessels surrounded by mononuclear phagocytes lymphocytes plasma cells and polymorphonuclear leukocytes and incorporated one or several tubules in various stages of injury up to actual necrosis Wolbach noted that these lesions were present also in scrub typhus and Rocky Mountain spotted fever but that in all three diseases the distribution was spotty and little renal parenchyma was involved[1] In the classic description of the pathology of RMSF Lillie observed that 12 of 17 cases had focal lesions with irregular interstitial and perivascular infiltration by lymphocytes in later cases often plasma cells and large lymphoid cells as well These lesions were especially marked at the corticomedullary junction Focal pericapillary and interstitial hemorrhages were identified in six cases Our study confirmed these observations and demonstrated by specific immunofluorescence that the distribution of the majority of the *Rickettsia rickettsii* was identical with that of the multifocal perivascular interstitial nephritis concentrated near the corticomedullary junction[20]

Another potential local effect of rickettsial infection on the kidney is thrombosis Wolbach described precisely this relationship in typhus fever with thrombosis of vessels in the focal interstitial lesions no lesions of large blood vessels and one case with small mural thrombi in small arteries of the pelvic submucosa with rickettsiae in the endothelium of the affected vessels[11] Our original study of ten cases of RMSF with histochemical staining for fibrin revealed thrombi only in vessels of a minority of the focal interstitial lesions and no glomerular thrombi[20] Subsequently we have investigated a case of fulminant RMSF (defined by Parker[21] as fatal within 3 to 5 days of onset) which showed fibrin thrombi in approximately half of the glomeruli Glomerular fibrin thrombi were also demon

nine cases[3] Absence of left ventricular dilatation indicated that severe myocardial failure was not the etiology of hypotension shock and death in these cases of RMSF

Pathologic studies of lung in rickettsial disease have demonstrated interstitial pneumonitis with alveolar walls containing mononuclear leukocytic infiltration[14 18 19 23 26 29 33] In cases which were not complicated by bronchopneumonia interstitial pneumonitis was manifested grossly by congestion and edema Further microscopic evidence for loss of vascular integrity are multiple foci of alveolar hemorrhage fibrin and edema Examination of lungs from cases of RMSF by specific immunofluorescence has revealed moderate to severe infection of the pulmonary microcirculation by *Rickettsia rickettsii* (see illustrative Case 2 below) thus providing a pathogenetic explanation for the interstitial pneumonitis and the increased pulmonary vascular permeability[33]

Cardiovascular and pulmonary pathophysiology in rickettsial diseases The studies already referred to convincingly exclude any significant contribution by the heart to the development of hypotension and peripheral circulatory collapse in the course of severe rickettsial infection but the role of the heart in the development of pulmonary edema a less common complication has been more difficult to clarify In his classic study of the typhus heart Woodward documented the fact that central circulatory failure and pulmonary edema were distinctly uncommon None of the 30 severely or critically ill patients he studied during the course of their illness had cardiac enlargement by physical examination a gallop rhythm distended neck veins or an enlarged liver He recorded serial measurement of venous pressure Values above 12 cm water were not seen and the average value was 8 cm water Radiographs were available in 12 patients and showed neither cardiomegaly nor pulmonary conjestion Electrocardiograms showed no striking deviations from normal Rales were heard frequently but usually in association with coarse rhonchi and were considered to be manifestations of tracheobronchitis or patchy bronchopneumonia both of which were often observed at necropsy

Pulmonary edem [illegible] h [illegible] nally been noted in scrub typhu [illegible] u [illegible] njunction with other findings of [illegible] he patients were critically ill or [illegible] the pulmonary edema was considered to be a manifestation severe rickettsial pneumonitis[6]

Pulmonary edema has been most frequently reported in RMSF and its pathogenesis is critical importance with regard to fluid ment A careful review of the case reports of the 13 patients Harrell originally described in study of peripheral circulatory failure re that five developed pulmonary edema during course of their illness[17] The episodes of nary edema all occurred in the second week of illness at the height of the changes in syste capillary permeability or a few days into th recovery period The administration of solutn containing colloid immediately preceded development of pulmonary edema in instance and an increase in plasma documented by the Evans Blue dye Distended neck veins were not observed howe and the one recording of venous pressure d an episode of pulmonary edema revealed a va of 10 cm H_2O A gallop rhythm was noted in one instance Treatment consisted of d administration and fluid restriction There clinical resolution of the pulmonary edema in 48 hours in four of the patients but the fi patient developed bacterial pneumonia died

A recent clinical study of the pulmonary ifestations in RMSF confirms and extends the observations[34] The records of all patients hospital documented to have RMSF betwe 1973 and 1976 were reviewed Nine of the patients had deterioration in pulmonary fu co during the first week of hospitalization with widening of the alveolar arterial oxygen d ence Seven developed radiographic infil and six developed pulmonary edema All were in markedly positive fluid balance and had received large amounts of fluid fol hypotensive episodes None of the patients third heart sounds cardiac enlargement ra graphically or electrocardiographic chan es of the patients with severe disease died within hours of hospitalization Diuresis in the o eight patients led to prompt improvement of exchange Radiographic and clinical gas pulmonary edema cleared within 48 hours

Since 1976 we have seen two additional one which illustrates the clinical presentation pulmonary involvement in RMSF and the which highlights the pathological changes

red cell casts) to support the occurrence of acute glomerulonephritis

Thus the major clinical abnormalities in renal function prerenal azotemia and ATN are the early or later consequences of the systemic vasculitis Recovery of renal function with prerenal azotemia is the rule and the potential for recovery from ATN with resolution of the vasculitis is suggested

Cardiovascular and pulmonary pathology in rickettsial diseases In general the heart in typhus fever RMSF and scrub typhus manifests negligible gross alterations and virtually universal microscopic interstitial mononuclear myocarditis Wolbach felt that inflammatory infiltration of the myocardium was diffuse because of its relationship to the most diffusely distributed blood vessels the capillaries that the order of severity of inflammatory infiltration was scrub typhus typhus and RMSF and that not much evidence of degeneration of heart muscle could be demonstrated[16] Myocarditis was noted in a series of eight autopsies of cases of RMSF by Wilson and Chowning in 1904[8] They noted a few epicardial petechiae dark fluid blood filling the right ventricle empty left ventricle and considerable round cell infiltration Following a number of case reports by a series of authors often citing myocarditis Lillie published the classic description of myocarditis in RMSF in his series of 17 cases[19] Grossly he noted that the right ventricle was more often dilated than the left but in the majority the status of the chambers was normal or contracted and that altogether gross changes were slight Microscopically two cases were normal 15 manifested interstitial infiltration of variable density chiefly by lymphocytes often with lesser numbers of plasma cells monocytes a few neutrophil or eosinophil leukocytes or mast cells Myocarditis was irregular and patchy often distinctly centered about small vessels and in interfascicular connective tissue Only two cases had focal coagulative necrosis of myocardial cells

In the definitive study of the pathology of typhus Wolbach stated that as a rule the left ventricle was contracted and the right moderately dilated[4] In six postmortem examinations performed soon after death in cases without significant bacterial complications myocardium showed pallor loss of consistency and yellowish streaks and points Acute valvular lesions and macroscopic mural thrombi were not detected Microscopic lesions which were observed in all 37 necropsies included slight degrees of edema focal and diffuse myocarditis with interstitial macrophages lymphocytes plasma cells few polymorphonuclear leukocytes and vascular lesions almost wholly restricted to capillaries and vessels of pre capillary size Large blood vessels in the heart and pericardium very rarely contained lesions Pathologic studies of the heart in scrub typhus have yielded essentially the same observations as in typhus fever and RMSF[26]

Besides myocarditis there have been few consistent pathologic alterations of the heart in the rickettsial diseases When present they have included few subendocardial mononuclear inflammatory foci pericardial fluid varying from none to moderate to rarely large amounts and an occasionally demonstrated focal inflammatory lesion involving a conduction bundle[3] or the Purkinje conduction system

The relationship of rickettsiae to the myocarditis has been unclear Much of this unsatisfactory state has been a result of the unreliability of the various Giemsa techniques to demonstrate rickettsiae Even in the hands of Wolbach who used the method to demonstrate rickettsiae successfully in many lesions of typhus and spotted fever rickettsiae could not be satisfactorily demonstrated in heart lesions of typhus fever Of 40 cases of RMSF in which Giemsa stain was reported to have been used to search for rickettsiae in heart only a single case was reported to contain rickettsiae within the cytoplasm of the endothelial cells of the subepicardial and interstitial capillaries[31] In contrast *Rickettsia rickettsii* were demonstrated in hearts of all eight untreated or inadequately treated cases of RMSF which were examined by a technique of deparaffinization trypsin digestion and specific direct immunofluorescence in our laboratory[32]

Rickettsia rickettsii were observed in capillaries venules arterioles and large vessels including coronary arteries in descending order of involvement Vascular infection with resultant vascular injury and increased permeability provides the probable pathogenetic mechanism for moderate myocardial edema Data on the same series of hearts with etiologically confirmed RMSF which suggested myocardial edema were increased heart weight in eight of nine cases and detectably increased interstitial volume in six of

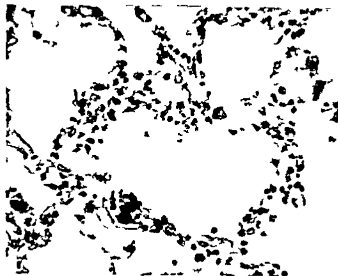

Fig 2 Photomicrograph of lung from Case 2 of RMSF Interstitial pneumonia is characterized by mononuclear cell infiltration of the alveolar septa Proteinaceous edema fluid fills the alveolar spaces (Hematoxylin-eosin stain original magnification ×220)

Fig 3 Photomicrograph of lung from Case ? of RMSF Brightly immunofluorescent *Rickettsia rickettsii* are vis within thickened portions of an alveolar septum (Flu resce isothiocyanate conjugated anti *Rickettsia rickettsii* glob fraction original magnification ×3?0)

respiratory infection was diagnosed and treated symtomatically Over the next two days she developed nausea vomiting high fever and malaise Physical examination at the time of admission showed a blood pressure 80/60 mm Hg and a pulse rate of 100 beats per minute She was oriented though lethargic and appeared acutely ill Physical examination showed no rash Scleral icterus was noted but without enlargement or tenderness of the liver The lungs were clear to auscultation and no signs of heart failure were observed Liver function tests were markedly abnormal with total bilirubin 15 mg/dl moderately elevated alkaline phosphatase and markedly elevated liver enzyme values The BUN was 91 mg/dl and serum creatinine was 4 8 mg/dl The serum sodium was 125 mEq/L serum calcium 6 8 mg/dl total protein 5 8 g/dl and albumin 3 1 g/dl Febrile agglutinins included a Proteus OX 19 titer of 1 20 Fluids were given as 5% dextrose in water alternating with normal saline at a rate of 3 000 ml per day and methylprednisolone was given intravenously 1 gm every 8 hours The blood pressure rose initially but she remained oliguric and her general condition deteriorated Thirty six hour after admission therapy with tetracycline was begun intravenously 500 mg every 8 hours Forty six hours after admission the patient became tated and hypotensive Two hours later a ardiorespiratory arrest occurred following an episode of vomiting the patient could not be resuscitated

Pertinent necropsy findings were multifoca interstitial pneumonitis bilateral pulm ma (Fig 2) associated with severe ricketts infection of alveolar capillaries (Fig 3) m mononuclear interstitial myocarditis and acu tubular necrosis with cortical interstitial ede and low regenerative tubular epithelium

Comment Although lacking extensive pulmo nary clinical and functional data this patient an excellent example of the pathologic and rick ettsiologic involvement of lungs heart and kid neys in RMSF Despite initiation of tetracycl treatment on her fourth day of illness she su cumbed to a severe rickettsial infection As su gested clinically by the persistent oliguria follow ing restoration of blood pressure to normal w intravenous fluids she had acute tubular at autopsy One of the most important manifesta tions of her disease was severe rickettsial infectio of the pulmonary microcirculation with alveolar edema Pulmonary edema w documented grossly and microscopically in face of only mild mononuclear interstitial myo carditis

Based on the pathological changes we h described in the heart and lungs and the lim clinical data referred to above it appears that pulmonary edema seen in RMSF is most o

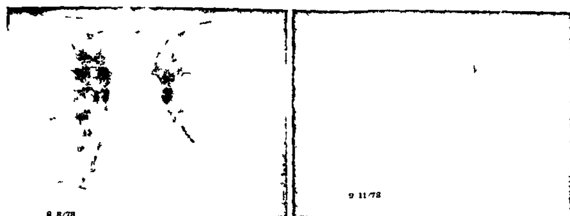

Fig 1 Chest radiographs in Case 1 of RMSF On the day of admission (left) heart size and pulmonary vascular pattern are normal After two days of parenteral fluid administration (right) heart size is unchanged but radiologic pattern of pulmonary edema is present

lustrative cases

Case 1 A 48 year old white housewife from mithfield N C removed a tick from her scalp n days before admission Three days later she eveloped severe headache nausea and fever hereafter she had daily fevers of 40 C and ntermittent vomiting Three days before admis on a red macular rash was noted on the trunk nd extremities including the palms and soles he was admitted to North Carolina Memorial ospital on September 8 1978 Physical examina on showed a blood pressure of 140/80 mm Hg nd a temperature of 40 C Pulse rate was 100 eats per minutes She was oriented and alert but ppeared weak and acutely ill A generalized aculopapular rash with petechial areas was oted on the trunk and extremities The lungs ere clear the neck veins were not distended and xamination of the heart showed no enlargement r gallop rhythm There was no peripheral edema o adenopathy and the neurological examination as normal Blood chemistries included sodium 33 mEq/L BUN 15 mg/dl creatinine 0 8 g/dl calcium 8 6 mg/dl total protein 6 5 /dl and albumin 3 5 g/dl The hematocrit was % and the platelet count 92 000/µl The pro rombin time and partial thromboplastin times ere normal The initial chest radiograph (Fig 1) as interpreted as normal A skin biopsy on the ay of admission examined by specific direct nmunofluorescence was diagnostic for Rocky Iountain spotted fever with *Rickettsia rickettsii* n dermal blood vessels

She was begun on treatment with intravenous hloramphenicol 100 mg every 8 hours and intravenous hydration with 5% dextrose in normal saline at a rate of 75 ml/hr On the second day after admission she developed progres sive shortness of breath over a period of several hours Examination revealed diffuse rales but the neck veins were not distended and no gallop rhythm was heard The blood pressure was 160/80 mm Hg Arterial blood gases revealed pH 7 52 PCO 22 torr and PO 30 torr Repeat serum total protein was 6 5 g/dl with albumin 3 0 g/dl The electrocardiogram showed sinus tachycardia and nonspecific ST segment changes A repeat chest radiograph was interpreted as showing pulmo nary edema (Fig 1) She was transferred to the intensive care unit where she was treated with oxygen furosemide and digoxin Within three days pulmonary gas exchange had improved and the rales and pulmonary infiltrate on chest radio graph had cleared Her recovery was unevent ful

Comment Fluid administration in this other wise stable patient led to the abrupt development of pulmonary edema in the absence of signs of heart failure or elevated systemic venous pres sure The predominance of infiltrates in the upper lobes is similar to that seen when pulmonary capillary wedge pressure is elevated—i e in car diogenic pulmonary edema—but might have occurred at only slightly increased pulmonary capillary wedge pressure in the presence of both a decreased intravascular oncotic pressure and altered pulmonary capillary permeability

Case 2 A 19 year old black female from Rock Hill S C was seen by her physician two days prior to hospitalization at which time an upper

non cardiogenic It typically occurs after vigorous fluid administration usually at the height of illness and is probably a consequence of an increase in pulmonary capillary permeability Confirmation of the pathogenesis of the pulmonary edema however will require more specific physiologic data including measurements of pulmonary capillary wedge pressures pulmonary capillary oncotic pressures and pulmonary interstitial oncotic pressures as estimated by the measurement of edema fluid protein concentration[3]

Conclusions

The documented changes in systemic capillary permeability and probable changes in pulmonary capillary permeability which we have discussed have definite therapeutic implications with reference to intravenous fluid therapy in severely affected patients The selection of fluids either colloids or crystalloids is particularly controversial in terms of predicting the effect on the *Starling forces* in the pulmonary circulation The use of crystalloids may cause both a small increase in intravascular hydrostatic pressure (PCWP) and by dilution a small decrease in intravascular oncotic pressure The net change in filtration pressure may be sufficient to favor transudation of fluid into the pulmonary interstitium Colloid administration may cause an increase in pulmonary intravascular hydrostatic and oncotic pressures but interstitial oncotic pressure may also rise if pulmonary capillary permeability to proteins is sufficiently altered favoring the development of pulmonary edema As noted five of the 13 patients reported by Harrell developed pulmonary edema after colloid was administered at the height of the illness

Among the conclusions that can be reached with certainty is the fact that pulmonary function is particularly at risk in severe RMSF Patchy areas of vasculitis and interstitial edema in the kidney or heart may cause little damage to renal tubular transport or myocardial contraction and in the systemic circulation may not impair flow or peripheral delivery of nutrients (at least until hypotension supervenes) These same pathologic changes in the pulmonary capillaries on the other hand may lead to an acute increase in lung water and impairment of gas exchange

The purpose of fluid administration in severe rickettsial infections is to expand intravascular volume and support blood pressure so that adequate perfusion of vital organs and peripheral tissues can be maintained during the acute phase of the vasculitis Care should be exercised to limit fluid administration (1) to avoid the accumulation of peripheral edema with the attendant risk of subsequent intravascular volume overload as vascular integrity is restored and (2) to minimize the risk of developing pulmonary edema particularly at the height of the illness when pulmonary capillary permeability may be significantly increased Monitoring of pressures in the pulmonary capillary circulation should be considered in the severely ill patient with hypotension to assist in the selection and use of intravenous fluids

The authors wish to thank Ms Barbara G Cain for [illegible] raphic assistance Mrs Jennie Lu Hollander for secretarial assistance and Dr James Maynard for providing Case 2 [illegible] ou tud

Case presentation

DR KIM FEHIR The patient was a 25 year old woman who was in entirely good health until five days before presenting to hospital when she was involved in an automobile accident in which her car was thrown into a spin and she struck her forehead and chest on the steering wheel She was treated in a nearby hospital emergency room for local chest bruising and tenderness chest and skull radiographs were normal Mild dyspnea on exertion developed at home and five days post trauma when she suddenly developed a persistent squeezing substernal chest pain accompanied by nausea vomiting and cold diaphoresis After 24 hours of pain she presented to the hospital complaining of substernal chest pain and also sharper pain aggravated by breathing

Her past medical history was remarkable for a five year history of heroin abuse for which she was taking methadone She was on no other medication had never taken oral contraceptives and was not recently pregnant Her only cardiovascular risk factor was a 24 pack year history of smoking

Initial physical examination revealed a moderately distressed young woman complaining of chest pain Pertinent physical findings included a blood pressure of 130/86 mm Hg without pulsus paradoxus a regular pulse of 96 and normal respirations Her chest wall showed no local bruising or tenderness Her lungs were clear without rales rhonchi rubs or wheezes On cardiac examination the point of maximal impulse was in the fifth intercostal space midclavicular line Her heart sounds were normal a soft ventricular gallop (S) and a pericardial friction rub was present There were no murmurs thrills carotid bruits jugular venous distention hepatojugular reflux hepatosplenomegaly cyanosis clubbing or peripheral edema

The chest radiograph showed a normal cardiac silhouette with a cardiothoracic ratio of 12/25 the electrocardiogram (Fig 1) showed normal sinus rhythm right axis deviation right bundle branch block and pathologic Q waves with ST elevation in Leads I L and V_1 to V_4 compatible with an acute anterior wall myocardial infarction Her initial creatine kinase (I U) was 2 390 and the remainder of her laboratory findings were unremarkable

Hospital course

DR DOLORES SHOBACK Her hospital c was initially complicated by the develc complete heart block requiring a t transvenous pacemaker for a period of five after which normal sinus rhythm returned creatine phosphokinase (CK) every four hours showed subsequent 2 080 1 930 1 760 650 and 588 which

ventricular pacing failed to elicit ventricular tachycardia

Five months after the original infarction the patient died suddenly while driving an automobile On her prior clinic visit she claimed to have taken her digoxin and procainamide faithfully

Clinical discussion

DR STEPHEN VLAY It is likely that this young woman's myocardial infarction was somehow related to the chest trauma which occurred one week before her occlusion Nonpenetrating trauma to the chest may injure almost any portion of the heart resulting in myocardial contusion, pericardial aneurysm or rupture There may be valvular injury or the trauma may bring about valvular dysfunction due to laceration or rupture of the valves Occlusion of a major coronary artery as a direct result of blunt trauma has been regarded as rare, and has been reported only in the presence of preexistent coronary artery disease In their series of 546 autopsy cases of nonpenetrating cardiac trauma Parmley and colleagues reported no instances of coronary occlusion although they

Fig 2 *Left* In the right anterior oblique (RAO) proje ti n l ft anterior descending coronary artery is occluded proximally *(arrow)* immediately after the takeoff of he f r t LAD diag nal branch The left circumflex system is normal. *Right* The RCA system is free of di ease

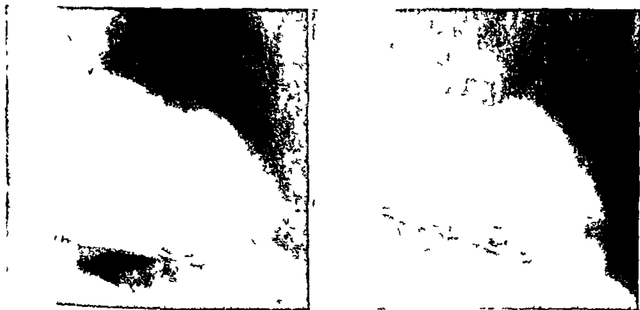

Fig 3 The left ventriculogram in the RAO projection is shown in diastole *(left)* and systole *(right)* Marked akinesis of the anterior wall apex and distal inferior wall is demonstrated with preservation of function in the proximal inferior wall.

sponded poorly to intravenous lidocaine and was exacerbated by oral quinidine Intravenous procainamide abolished the dysrhythmia and an oral preparation was substituted An electrophysiologic study to assess the degree of ventricular irritability was undertaken with the patient receiving procainamide and demonstrating therapeutic serum levels Four sites in the ventricle studied for the repetitive ventricular response during sinus rhythm and two sites studied during

allels that reported by Stern and associates[4] in which a young man in his 30s sustained an anterior myocardial infarction after an auto accident and at angiography was found to have complete occlusion of the proximal LAD with otherwise normal coronary arteries In both reports there were no apparent risk factors of coronary occlusion and no evidence of connective tissue disease

DR BLUMENTHAL The severity of chest wall trauma does not appear to correlate with the occurrence of coronary occlusion following trauma as was seen in our patient [3] An elastic compressible nonfracturing rib cage may result in more severe cardiac damage than one that fractures and dissipates mechanical energy [5, 24 …] Many of the cases [3, 8, 2] however were associated with local ecchymoses or rib fractures The most violent injury was an auto accident reported by Heyndrickx and colleagues[11] in which a patient suffered major trauma to the thoracic cage and sustained rupture of the right coronary artery

DR BERNADINE BULKLEY The etiology of myocardial infarction due to nonpenetrating chest injury is not entirely clear Studies in the previously reported cases suggest varied etiologies (1) atherosclerotic heart disease either diffuse or isolated complicated by hemorrhage into a plaque or spasm (2) coronary thrombosis due to direct vascular trauma (3) spasm in normal coronary arteries (4) frank rupture of the vessel (5) dissecting aneurysm and (6) coronary embolization The presence of coexisting coronary artery disease has been raised by some as a necessary predisposing factor In the 16 cases under analysis however only four had evidence of extensive atheromatous disease Another four were described as having slight or insignificant lesions Unfortunately in some of the earlier cases the degree of obstruction was not quantitated How important a role slight or insignificant lesions may have played in the subsequent myocardial infarctions remains a matter [illegible] speculation Of cases without other le[illegible]on [illegible] eight were documented by angiography Thu[illegible] in thi[illegible] small group of patients preexi[illegible] [illegible] tery disease was not a [illegible] [illegible] duction of coronary occlu[illegible] [illegible] [illegible]uma

Patients with [illegible] [illegible]ease however may be at a greate[illegible] [illegible] injury related to blunt trauma as con[illegible] [illegible] a person with normal coronary arteries when one considers that diseased and brittle vessels lying on the surface of the heart may be subjected to direct damage Levy[7] believed this to be the case with the 49 year old woman in whom he observed hemorrhage within the plaque and seepage of blood through the intimal lining with thrombus formation Moritz[3] stated in his review that plaques in atherosclerotic coronary arteries are often richly vascularized with newly formed thin walled capillaries that are inadequately supported by the surrounding liquid debris and suggested that such vascular plaques are subject to spontaneous or traumatically induced rupture into the lumen of the diseased artery

DR VLAY In a 25 year old woman however one would suspect that there is less likelihood of preexisting coronary disease Thrombus has been suspect in the pathogenesis of traumatic coronary artery occlusion Seven of the nine autopsied cases described thrombotic occlusion of the coronary vessel One may speculate that shearing forces during the traumatic episode may produce a small intimal tear which subsequently acquires platelets fibrin and other clotting system components until thrombosis is complete Spasm with subsequent thrombus formation also may occur in response to local injury although documentation of this is not available Such a mechanism was proposed after blunt trauma to the chest of laboratory animals [3] it was felt that localized blows transmitted to the precordium induced coronary spasm Gertz[11] has presented preliminary evidence that spasm results in endothelial damage using a feline model Spasm produced in the basilar as well as in the coronary arteries resulted in local damage and subsequent thrombosis

DR BLUMENTHAL The findings in some patients with myocardial infarction after trauma but with normal coronary arteries on angiography [illegible] has raised the question of whether the injury was ever to the coronary vessel but was rather a severe myocardial contusion Myocardial contusion has been easily produced experimentally [illegible] and is frequently identified by ECG elevated CK and other cardiac isoenzymes or demonstrated by extraction or lack of uptake by a variety of radionuclide tracers [illegible] Nevertheless the identification of normal coronary arteries at angiography weeks to months after the infarct

Angiogram	Autopsy	Atherosclerotic coronary artery disease	Between trauma & symptoms of MI
	Thrombotic occlusion of LAD with large infarct	Yes (extensive)	9 days
	Organized thrombus LCA recanalized Death due to RCA occlusion ten months after original infarct	Yes (extensive)	1 hour
	Occlusion by thrombus 1 cm from origin	Yes (slight)	Immediate
	Traumatic dissecting aneurysm of LAD	Yes (insignificant)	6 days
	Anteroseptal MI occlusion LAD by thrombus	Yes (extensive)	Immediate
	Occlusion of LAD at point of narrowing with hemorrhage into wall and small red fibrinous thrombus blocking lumen	Yes (extensive)	2 hours
	Large organizing thrombus in left circumflex	Yes (insignificant)	Immediate
Normal coronary arteries		No	10 hours
	Complete rupture of RCA cm from orifice covered with a small fresh thrombus	Yes (slight)	Immediate
Total obstruction in proximal LAD		No	Immediate
Complete occlusion left circumflex		No	[illegible] hour
Normal coronary arteries		No	Immediate
Total occlusion LAD 1 cm from origin		No	Immediate
Severely obstructed RCA 1 cm beyond its origin		No	Immediate
Total occlusion RCA 1 cm beyond its origin		No	Immediate
Total obstruction in proximal LAD	Proximal LAD obstructed by fibrous plaque with recanalization	No	5 days

did observe nine cases of complete rupture of a major coronary artery and a tenth involving an intimal tear Sporadic reports of myocardial infarction following blunt trauma and substantiated by autopsy or angiography have appeared in the medical literature over the past 40 years

Myocardial infarction after blunt chest trauma however as may have occurred in this young woman is rare We could identify only 15 prior reported cases with documentation by autopsy or angiogram and findings in these patients are summarized in Table I Approximately 25 other reports suggesting myocardial infarction following nonpenetrating chest injury were excluded from this review due to lack of angiographic or autopsy documentation The 16 patients summarized in Table I included 13 men and three women with a mean age of 38 years (range 10 to 62 years) Eight of the 16 had atherosclerotic coronary artery disease which was described as extensive in four of them The anterior descending branch of the left coronary artery (LAD) was involved in ten cases the left circumflex was involved in two cases and the right coronary was involved in four cases

The presently described case most closely par

transmural anteroseptal and apical transmural myocardial infarct Her coronary arteries had normal takeoff from the aorta and showed no evidence of dissection or aneurysm formation Her proximal left anterior descending coronary artery was totally occluded by a fibrous plaque compatible with atherosclerosis or with a previous thromboembolic event with subsequent organization (Fig 4) The remainder of her coronary arteries and her aorta were completely free of atherosclerotic plaque There was no evidence of recent infarction or coronary thrombosis to account for the terminal event

DR BLUMENTHAL Dr Bulkley how do you account for the delayed presentation of the infarction?

DR BULKLEY Most unclear and atypical in this young patient is the occurrence of the infarct five days after the blunt trauma Of the previously reported 15 cases only two others had evidence of delayed myocardial injury after the chest trauma one 6 and one 9 days after the traumatic event The ECGs and the pattern of serum creatine kinase elevation in our present patient support the clinical history suggesting that the infarct occurred five days after the trauma Initially the electrocardiogram revealed an acute infarct with ST T changes that evolved with loss of R waves in the precordium Although the precise etiology remains unknown, the precipitating event in this patient was assumed to be a coronary thrombosis and/or embolism Unfortunately morphologic findings five months after the event do not entirely resolve the question of etiology An organized thrombus or embolus may be indistinguishable from a fibrous atherosclerotic plaque of long standing duration Considering the patient s youth and absence of symptoms prior to the event it seems likely however that the high grade narrowing of her coronary artery by fibrous plaque seen at autopsy in the setting for otherwise normal coronary arteries may well have been related to a thrombotic occlusion Thus the histologic changes in her coronary artery are compatible with although not diagnostic of a prior thrombotic event The autopsy findings do provide evidence however that there was a coronary event related to the infarct and that the event was not a primary coronary dissection contusion or laceration Furthermore the autopsy findings show [illegible] rmality only in the left anterior descending coronary artery [illegible] this not the vessel most often involved by bl[illegible] chest trauma?

DR VLAY In ten of the 16 cases reported (63[illegible]) the vessel involved after blunt chest trauma causing myocardial infarction was the a[illegible] descending branch of the left coronary artery The anatomical location of this artery very likel[illegible] makes it particularly susceptible to the effects of trauma Noteworthy however is the predominance of involvement of this artery in cases of coronary artery embolization and dissection Explanations advanced for the predilection of the left coronary artery in these latter conditions of embolism have included (1) the larger caliber of the left coronary artery compared to the right and (2) the geometry of the left coronary arter[illegible] branches making the left anterior descendi[illegible] branch more liable to occlusion Arguments against a left predominance include the fact tha[illegible] (1) a right coronary embolus may not be fatal or may go unrecognized and that (2) right occlusion may be more distal with less loss of myocardial tissue With coronary artery dissection the left anterior descending coronary artery is again the most frequently involved usually within two centimeters of the aortic ostium but the reason for this predominance is unclear

DR BULKLEY Only certain types of trauma seem to lead to this unfortunate myocardial injury Not surprisingly automobile accide[illegible] were implicated in eight of 16 (50%) reported cases and many of the anecdotal accounts involve steering wheel trauma Such injuries might be prevented by wearing shoulder harness seat belts Assault with a fist was responsible for a[illegible] other three (19%) cases The other 31% were accounted for by sporting activities and industrial accidents In our patient steering wheel injury albeit mild appeared to be the culprit The findings in this patient and in several others reported sug[illegible] that traumatic coronary artery disease should [illegible] least be entertained in the patient with se[illegible]ere a[illegible] persistent chest pain after chest trauma even of [illegible] mild degree of severity Although at the prese[illegible] time there is little evidence that early interven[illegible] tion might alter the course of this event ea[illegible] recognition of an impending coronary occlu[illegible] in at least the few patients with delayed myocardial injury may offer the potential for reparative intervention

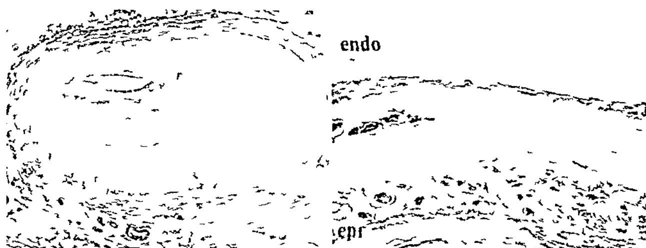

Fig 4 *Left* Histologic section from the proximal left coronary artery showing a near total occlusion by a fibrous plaque (Hematoxylin and eosin original magnification ×30) *Right* Histologic section through site of anterior wall infarction showing a transmural scar a thickened endocardium *(endo)* overlying the infarct and organized epicardial *(epi)* adhesions compatible with a focal pericarditis (Hematoxylin and eosin original magnification ×30)

not sufficient to rule out acute thrombotic ents as precipitating the acute infarct Also vere coronary spasm as the result of the trauma ight result in infarction but would show normal oronaries angiographically although spasm is ften noted at a site of coronary narrowing oronary artery embolus similarly cannot be xcluded The findings in our patient are clearly coronary event associated with an infarct in the bnormal vascular distribution rather than the esult of a contusion Another unusual cause of raumatic myocardial infarction also unlikely in ur patient is a frank rupture of a coronary rtery [1] In one patient in which it was eported [11] an acute infarct resulted from a com lete rupture of the right coronary artery asso iated with laceration of the pericardium and erniation of the heart the latter preventing ericardial tamponade and allowing brief surviv l

DR VLAY Dissection of a coronary artery may lso result from trauma [6] however dissection was dentified in only one of the 16 patients reported ne might suggest that a small intimal tear radually expanded over the course of six days nd then suddenly proceeded to dissection It is enerally believed however that coronary dissec ions have a rapidly fatal course and among atients dying of coronary dissection reported in he literature [14] trauma was an infrequently associated event A final mechanism that must be considered is coronary embolus secondary to mural thrombosis from an injured left ventricular myocardium Levy cites Randerrath s case of the 34 year old soccer player who was struck in the chest by a ball and collapsed with pallor and cold diaphoresis with death on the following day The autopsy revealed a recent small apical aneurysm with fresh mural thrombosis An embolus was identified in both the LAD and the RCA

In summary we have a 25 year old woman with flush occlusion of the anterior descending branch of the left coronary artery and infarction in its distribution who subsequently had a sud den death Due to the absence of other angio graphic lesions in her coronary tree the most likely etiology is thrombosis related to an injury to the artery or an embolic event The cause of death most probably was a ventricular arrhyth mia although infarction must not be excluded Dr Bulkley will now present the pathologic findings

Discussion of pathologic findings

DR BULKLEY At autopsy the only abnormali ties were present in the patient s heart and lungs Her lungs were heavy and showed evidence of diffuse pulmonary congestion and focal areas of intralveolar edema Her heart weighed 350 grams and had left ventricular dilatation and a large

mal or absent and there is instead a predominant systolic dip (X descent)[3]

Paradoxical pulse is present as a rule in cardiac tamponade The principal exceptions are those instances in which it may be obscured by arrhythmia or by other complicating features In constrictive pericarditis on the other hand paradoxical pulse is usually of lesser degree than in tamponade and may be absent

Kussmaul s sign occurs in some patients with constrictive pericarditis although probably not the majority In cardiac tamponade however if strictly defined Kussmaul s sign occurs rarely at most perhaps never Reported instances of Kussmaul s sign in tamponade are numerous but none are substantiated by direct pressure records such reports probably result from failure to recognize associated constrictive pericarditis in some instances while in others an inspiratory increase in amplitude of venous pulsation may be mistaken for a true rise in central venous pressure Still other cases represent instances where the sign is elicited with an instructed deep inspiration to which the patient responds by performing Valsalva s maneuver The differences in special features are perhaps not so widely appreciated as they might be and the principal reason for this may be that there has been no readily understandable or generally accepted explanation for them Indeed the mechanisms of the special hemodynamic features themselves especially paradoxical pulse and Kussmaul s sign have not been adequately understood *An additional difficulty is that clini*cal assessment is not so accurate or quantitative as direct pressure records in assessing these signs Further the classification of patients is often difficult because the objective diagnosis of either cardiac tamponade or constrictive pericarditis requires a combination of clinical hemodynamic and anatomic pathological data which are often not available in the clinical setting

Objective diagnosis of tamponade and constriction

The objective diagnosis of cardiac tamponade defined as a condition in which there is compression of the heart by fluid in the pericardial space under increased pressure requires the measurement of an elevated level of intrapericardial pressure and of correspondingly elevated levels of pressure within the chambers of the heart in diastole A further requirement i the return of hemodynamic measurements to normal after removal of enough pericardial fluid to reduce the intrapericardial pressure to normal Constrictive pericarditis is best defined as a condition in which there is compression or restriction of the heart by the pericardium either by the visceral layer or by an adherent parietal layer with hemodynamic abnormalities including elevated levels of diastolic pressure in the cardiac chambers which return to normal after surgical removal of the pericardium

It is often difficult to meet these diagnostic criteria in clinical practice Patients who are suspected of having cardiac tamponade because of the presence of pericardial effusion and elevated levels of venous pressure may be shown by hemodynamic study to have instead one of several other conditions alone or in combination Some have right sided congestive heart failure due to valvular or myocardial disease with increased amounts of pericardial fluid which is not under increased pressure and represents simply one site of accumulation of excess extracellular fluid Others especially patients on chronic dialysis for renal failure have predominantly fluid overload and left ventricular failure with an associated pericarditis and pericardial effusion of lesser importance A few usually on the basis of neoplastic disease have superior vena caval obstruction rather than tamponade Finally some patients have a combination of tamponade and constriction due to pericardial *fluid under increased pressure* associated with constriction of the heart by the visceral pericardium (epicardium) this condition (effusive constrictive pericarditis) can only be demonstrated objectively by showing that the venous pressure level remains elevated with other features consistent with constriction after the intrapericardial pressure is reduced to normal by removal of fluid[3]

Observations in subacute constrictive pericarditis

Patients with effusive constrictive pericarditis usually have a subacute course measured in weeks or months rather than the period of years which is frequently seen in chronic constrictive pericarditis Hemodynamic studies in these patients have provided insight *into the* basis for the differing patterns of special hemodynamic features of tamponade and constriction In general they have features similar to those of tampon

Fundamentals of clinical cardiology

On the elastic and rigid forms of constrictive pericarditis*

E William Hancock M D
Stanford Calif

The effects of pericardial disease on the circulation result essentially from compression (restriction) of the heart making it more difficult for the heart to fill with blood during diastole The function of the heart during systole does not appear to be impaired in most cases The cardiovascular system typically achieves a compensation for compressive pericardial disease by increasing the central venous pressure to a level at which adequate filling of the heart in diastole can still occur despite the degree of restriction which the pericardial disease imposes Thus except in the most severe or the most rapidly developing cases where compensation is inadequate or in cases in which there are additional abnormalities of fluid balance or in the function of the heart or circulation the clinical and hemodynamic picture of compressive pericardial disease reflects essentially a sustained elevation of central venous pressure In this respect the two classical pericardial disorders cardiac tamponade (compression of the heart by pericardial fluid under increased pressure) and constrictive pericarditis (restriction of the heart by a thickened and adherent pericardium) are identical

Special hemodynamic features of pericardial disease

In compressive pericardial disease there are in addition to the elevated level of venous pressure four principal hemodynamic features which although not unique to pericardial disease are somewhat distinctive and are helpful in the clinical differentiation of pericardial disease from other disorders which may also cause elevated levels of venous pressure These features are (1) the occurrence of nearly equal levels of pressure in all chambers of the heart during diastole (2) the pattern of an early diastolic dip and later diastolic plateau in the ventricular pressure waveform and the corresponding prominent early diastolic dip in the atrial pressure waveform (3) the exaggerated variation in systemic arterial pressure with respiration (paradoxical pulse) and (4) the rise in venous pressure with inspiration (Kussmaul's sign)

Equilibration of intracardiac pressure levels in all cardiac chambers in diastole is a feature common to cardiac tamponade and constrictive pericarditis since both forms of pericardial disease typically produce compression which is symmetrical around the entire heart However the dip plateau waveform the paradoxical pulse and Kussmaul's sign are known to occur in somewhat different patterns in cardiac tamponade than in constrictive pericarditis

Hemodynamic differences between tamponade and constriction

The dip plateau pattern in the ventricular pressure waveform is a typical feature in constrictive pericarditis. In cardiac tamponade on the other hand there is little or no early diastolic dip pressure in the ventricle falls only partially during the early relaxation phase of the cardiac cycle and the plateau of elevated diastolic pressure is present from the beginning of diastole Correspondingly the prominent early diastolic dip (Y descent) is a feature of the venous pressure waveform in constrictive pericarditis but not in cardiac tamponade where the Y descent is mini

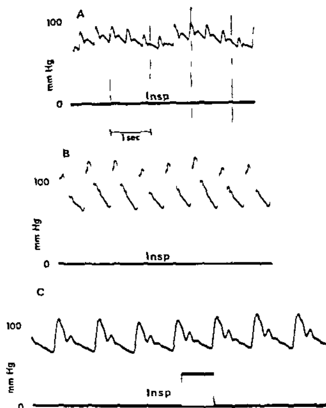

Fig 2 Varying degrees of paradoxical pulse are seen in direct pressure recordings from the aorta in patients with three types of compressive pericardial disease The three patients are the same as those illustrated in *Fig 1* At the top (*A*) in cardiac tamponade respiratory variation in arterial pressure is exaggerated a typical paradoxical pulse In the middle (*B*) in subacute constrictive pericarditis the respiratory variation is less but still slightly exaggerated for quiet respiration At the bottom (*C*) in chronic calcific constrictive pericarditis only an instructed deep inspiration is followed by an appreciable fall in pressure none could be appreciated during quiet uninstructed breathing The instructed deep inspiration is indicated by *Insp*

cle which is analogous to a rigid shell surrounding the heart At the beginning of diastole when the heart is least full it is comfortably smaller than the volume of the shell and is not constricted Thus as the ventricular myocardium relaxes the pressure in the ventricle falls rapidly to a minimum level near zero The combination of the high venous pressure and the unrestricted heart results in a rapid rate of blood flow into the ventricle in early diastole As the ventricle enlarges it reaches the fixed volume of the shell and from this time through the remainder of diastole the heart is severely restricted Any further filling during the restricted phase of diastole would be accompanied by a steep rise in pressure in the ventricle In such cases virtually all of the filling takes place in early diastole restriction comes into play abruptly and the plateau of the pressure recording represents a phase in which little or no further filling takes place

In cardiac tamponade the heart is compressed throughout the cardiac cycle This may be inferred from the pressure recording in the pericardial space which shows an elevated pressure level throughout the cycle The smaller size of the heart in systole does result in some decompression but the degree of compression is more constant and less dependent on the size of the heart than it is with the rigid shell type of constriction With tamponade therefore, the heart is compressed from the beginning of diastole The pressure in the ventricle does not fall to a normal level near zero, in early diastole but falls only to a level slightly above the pressure level in the pericardial fluid Filling of the ventricle is impeded in early diastole nearly as much as in later diastole flow into the ventricle takes place throughout diastole and the pressure waveform shows no early diastolic dip

The lesser prominence of the dip plateau waveform in patients with effusive constrictive pericarditis can be explained as the result of a degree of associated tamponade in such cases. Its similar lack of prominence in some patients with subacute constrictive pericarditis, even in the absence of an element of tamponade or of any pericardial effusion at all suggests another explanation Rather than a rigid shell with a fixed volume the patients with subacute constriction may be considered to have a fibroelastic type of constriction analogous to elastic rubber band wrapped around the heart Such an elastic constriction would compress the heart continuously throughout the cardiac cycle in the same manner as a tense pericardial effusion Thus the pattern of impedance to filling and the ventricular pressure waveform in subacute fibroelastic constrictive pericarditis with or without effusion might be expected to resemble that of cardiac tamponade as much or more than it would resemble that of a chronic rigid shell type of constrictive pericarditis

Mechanism and significance of the venous pressure waveform

The diastolic portion of the central venous pressure waveform reflects directly the pressure

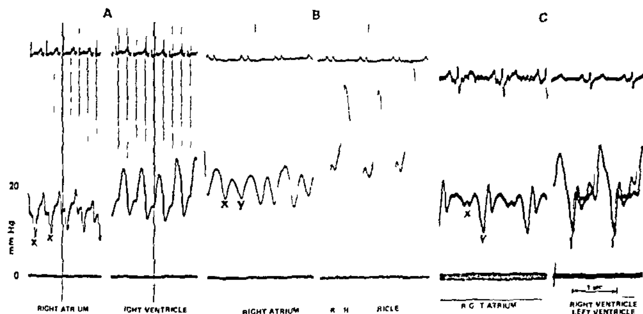

Fig 1 Contrasting waveforms are seen in pressure recor[illegible] the ri[illegible]t atrium and ri[illegible]ht ventricle in patients with three types of compressive pericardial disease On [illegible] in a 1[illegible] year old woman with cardiac tamponade due to leukemia the ventricular waveform [illegible] early and late diastolic pressure level and an inconspicuous dip plateau pattern while the atrial wav[illegible] prominent systolic (X) descent and absence of the early diastolic (Y) descent In the middle (B) in a [illegible] an with idiopathic subacute constrictive pericarditis without effusion the ventricular pressure [illegible] prominent dip-plateau pattern the atrial *pressure waveform shows approximately equal X and Y de[illegible] M or W contour On the right (C)* in a 49 year-old man with idiopathic chronic calcific [illegible] the ventricular pressure waveform shows a prominent dip plateau pattern the atrial pressure [illegible] shows a predominant early diastolic descent (xY pattern) All records are at the same paper speed and [illegible]

de even though their disease process and its management is essentially that of constriction The dip plateau in the ventricular pressure wave form is present but the dip is not so deep not approaching the zero level as it is in classical chronic constrictive pericarditis The venous pressure waveform usually shows a predominant systolic dip with a lesser but still present early diastolic dip (Xy) or a form with approximately equally prominent systolic and diastolic descents (XY) After removal of the fluid when only the constrictive element remains the early diastolic dip becomes more prominent in both the ventricular and the atrial pressure waveforms

Paradoxical pulse is consistently present in effusive constrictive pericarditis resembling cardiac tamponade in this respect It is relatively little affected by removal of the fluid Kussmaul s sign may occur in effusive-constrictive cases but is probably less frequent than in chronic constrictive disease Patients with subacute noncalcific constrictive pericarditis even in the absence of effusion also tend to show patterns of the special hemodynamic features which are intermediate between those of tamponade and classical constriction In this regard Wood contrasted active and inactive cases of tuberculous pericarditis while Kesteloot and Denef emphasized the special features of subacute constrictive epicarditis

Thus the differing hemodynamic features in acute cardiac tamponade and chronic constrictive pericarditis represent the two extremes of a spectrum of cases In the middle are patients with subacute constriction often associated with various degrees of pericardial effusion who show intermediate patterns of the special hemodynamic features Figs 1 and 2 illustrate the spectrum of atrial and ventricular pressure waveforms and of the paradoxical pulse

Mechanism and significance of the dip plateau waveform

The dip plateau waveform of the ventricular pressure recording in constrictive pericarditis is best understood as resulting from a type of mechanical impedance to the filling of the ventri

Table I Comparison of the frequency and relative prominence of several clinical and hemodynamic features in three types of compressive pericardial disease

	Tamponade	*Subacute (fibroelastic) constriction*	*Chronic (rigid shell) constriction*
Pericardial effusion	present	often present	absent
Pericardial calcification	absent	usually absent	often present
Abnormal P waves or atrial fibrillation	absent	usually absent	often present
Dip-plateau pattern	inconspicuous	moderately prominent	prominent
Venous waveform	X or Xy	Xy or XY	XY or xY
Paradoxical pulse	prominent	moderately prominent	inconspicuous
Kussmaul s sign	absent	usually absent	occasionally present
Early diastolic sound	absent	usually absent	often present

The early diastolic sound of constrictive pericarditis

The early diastolic sound (pericardial knock) of constrictive pericarditis is related to the dip plateau pressure waveform in the ventricle occurring near the end of the rapid filling phase in early diastole [1] The sound is present frequently in chronic constrictive pericarditis infrequently in subacute constrictive pericarditis and rarely if ever in cardiac tamponade These differences are understandable in terms of the differing prominence of the dip plateau pattern in these conditions The early diastolic sound may therefore be considered a sign of the rigid shell type of constrictive pericarditis

Clinical implications

The clinical picture of constrictive pericarditis has changed in recent years Tuberculosis is a less frequent cause than in the past and the chronic calcific type of disease often due to tuberculosis in the past is now less frequent than the subacute noncalcific form The majority of cases of constrictive pericarditis today are idiopathic (including those thought to follow viral infection) while smaller numbers occur after radiation rheumatoid arthritis bacterial and fungal infections chronic hemodialysis cardiac surgery and other conditions Constrictive pericarditis occurring in these latter conditions is in general likely to be recognized in the acute or subacute stage Thus the features described here as being characteristic of subacute fibroelastic constriction are found in many of the patients who are seen now with an initial presentation of constrictive pericarditis

The clinical similarity of fibroelastic constriction to cardiac tamponade and frequent association with pericardial effusion makes the differential diagnosis between constriction tamponade a difficult one in many instances The distinction is a vital one because the cho between pericardiocentesis pericardiostomy pa rietal pericardiectomy or visceral pericardial stripping as well as the evaluation of the resul of any of these forms of treatment depend accurate assessment of the nature of the c sive process Measurements of intracardiac and intrapericardial pressures before and removal of pericardial fluid are more a than is clinical assessment in answering th questions Study of the pressure waveforms well as the levels of pressure is important Table I summarizes the distinguishing points

Finally the differentiation of elastic and types of compressive pericardial disease may be useful step toward understanding the mechanism of paradoxical pulse and Kussmaul s sign tions which have been so interesting to c and physiologists for so long but which have been so difficult to answer clearly

Summary

This article discusses a thesis regarding the pathophysiology of constrictive pericarditis thesis is that there are two forms of constrictio one being elastic and the other more analogou a rigid shell The two forms of constriction considered to cause different patterns of diagnostic signs of constriction The elastic is similar to cardiac tamponade and is assoc with prominent paradoxical pulse and syste descent in the venous pressure waveform. T rigid shell type has less prominent paradoxical pulse and a more conspicuous diastolic descent

waveform in the corresponding ventricle because these chambers are in unimpeded communication in diastole. The prominent early diastolic dip in the venous pulse in constrictive pericarditis thus reflects the brief period of unimpeded blood flow into the ventricle in early diastole. Its absence in cardiac tamponade reflects the presence of compression of the heart early in diastole as well as throughout the rest of the cardiac cycle and thus the absence of a conspicuous phase of rapid filling in early diastole. Patients with subacute fibroelastic constriction are likely to show intermediate degrees of prominence of the early diastolic dip.

The systolic portion of the venous pressure waveform is influenced by several factors. There is a fall in pressure related to the descent of the ventricles due to ventricular contraction. A fall in pressure is also related to relaxation of the atria in systole following contraction of the atria just before ventricular systole. Patients with constrictive pericarditis usually show a normal systolic (X) descent if they have sinus rhythm and the venous pressure shows an XY waveform (resembling a W or M). Those with atrial fibrillation lose much of the systolic descent and usually show an xY waveform.

In cardiac tamponade there is a special circumstance owing to the phasic change in pressure in the intrapericardial space. Intrapericardial pressure falls in systole because of the degree of decompression resulting from the smaller size of the heart. Right atrial pressure falls correspondingly in systole, the two waveforms are often closely parallel throughout the cardiac cycle, indicating their interdependence. Thus an X or Xy is the characteristic venous pressure waveform in tamponade.

Mechanism and significance of paradoxical pulse

Paradoxical pulse occurs by various mechanisms and in a variety of conditions other than compressive pericardial disease. The mechanism by which it occurs in pericardial disease has not been adequately understood. A variety of plausible theories have been offered and it appears that various factors may play a role. It has been accepted, however, since the experimental studies of Shabetai and associates, supported more recently by echocardiographic studies, that paradoxical pulse in cardiac tamponade is associated with a normal or even exaggerated increase in venous return to the right side of the heart during inspiration. There is a simultaneous decrease in filling of the left side of the heart with inspiration. The increase in venous return appears indeed to be a necessary part of the mechanism of paradoxical pulse in pericardial disease.

Occurrence of the increases in volume of the right heart chambers with inspiration depends on the transmission of the inspiratory fall in intrathoracic pressure to the interior of the heart. In cardiac tamponade this transmission occurs in a normal manner, probably because the pericardium is flexible and the pressure changes are well transmitted through the fluid. In constrictive pericarditis, on the other hand, the increase in venous return with inspiration may not occur to the normal degree because the pericardium takes the form of a rigid shell and the intrathoracic pressure variations are not transmitted to the interior of the heart. Thus the absence of paradoxical pulse in constrictive pericarditis may reflect loss of the normal inspiratory augmentation of venous return.

Patients with subacute fibroelastic constrictive pericarditis might be expected to transmit intrathoracic pressure variations to the interior of the heart more faithfully than the chronic cases who have a constrictive disease that is more analogous to a rigid shell. Paradoxical pulse would therefore be expected to be more conspicuous in the subacute cases.

Mechanism and significance of Kussmaul's sign

Kussmaul's sign may also be considered a sign of failure of transmission of intrathoracic pressure variations to the interior of the heart. The lowered intrathoracic pressure with inspiration draws more venous return to the intrathoracic venae cavae and right atrium, but in the presence of the rigid shell type of pericardial disease there is no associated decrease in the compression of the heart, and the increased right atrial filling is manifested as a rise in right atrial and central venous pressure. Thus Kussmaul's sign would not be expected in cardiac tamponade; it might occur in some instances of fibroelastic constriction but would be expected frequently only in the chronic rigid shell type of constrictive pericarditis.

Appraisal and reappraisal of cardiac therapy

Edited by Arthur C DeGraff and Julian Frieden

Diet in the treatment of hyperlipidemia

Norton Spritz M D
New York N Y

The possibility that alteration in diet may affect the risk for coronary artery disease is based on several observations First it is generally true that the diet of those nations with higher prevalence of atherosclerotic disease differs in several respects from that consumed in nations of low risk for this group of diseases[1] The first contains more total fat more saturated fat more cholesterol and total calories Second within populations with high prevalence for vascular disease the risk among individuals for clinical disease relates to their individual levels of plasma lipids and dietary alterations produce lowering of these levels toward apparently more favorable levels On the basis of these facts it would seem likely that both for populations as a whole and for individual patients changes in diet from their present high fat high calorie high cholesterol high saturated fat diet would be advantageous and should be expected to lessen the high rate of coronary vascular and other atherosclerotic diseases seen in American and other high risk populations For reasons that will be discussed below however an unequivocal demonstration that such changes are of advantage has not been achieved and several lines of evidence raise doubts about the efficacy of such changes for the population and have made uncertain the criteria for selection of individual patients in whom such diets should be prescribed

In contrast to the association between diet and vascular diseases seen when populations are compared to one another the role of diet as a factor for either the level of plasma lipids or the risk for vascular disease for individuals within a given population has not been established With t exception of the Tarahumara Indians who ha very low plasma and dietary cholesterol[2] carried out in Hawaii[4] Michigan[5] Framingham Massachusetts[6] as well as in Israel and Grea Britain[8] have failed to show a relationshi between prior diet and the risk of vascular di — for individuals within this wide range of popula tion groups While inability to demonstrate relationship between diet and disease or value for plasma lipids may relate to problems i assessing diet histories methodologic problems in plasma cholesterol measurement or the fact i plasma cholesterol and/or coronary heart dis are determined by a variety of variables of whi diet is only one these studies do not provide i themselves evidence that risk of coronary arter disease or cholesterol concentration within population is determined in an important way b diet

Similarly studies in which diet has been altered experimentally in man to determine the effect o such alterations on the risk of coronary arter disease have been equivocal While these and other dietary intervention studies ha shown that lipids can be lowered under situations it has been difficult to demonstrat that the lipid lowering has an effect on mortality In studies carried out in Los Angeles Norway[1] involving approximately 1 000 men f l lowed for eight and 11 years plasma cholesterol was lowered in the group given a low fat low cholesterol high polyunsaturated fat die by about 15% compared to controls and there wa an apparent decrease in the numbers of c coronary events Yet in neither study at a time was mortality lower in the diet gro compared to the controls This lack of effect c mortality is similar to the findings in seven studies in which plasma lipids were lowered b drugs

is not clear however whether a subset of the population either with normal or high plasma levels is more sensitive to cholesterol intake The major source of cholesterol in our diets is eggs and each egg contains about 200 mg of cholesterol thus a diet restricted in cholesterol below 300 mg a day greatly limits the number of eggs that can be consumed

The amount and nature of the dietery fat also affects plasma cholesterol levels It is well established that the cholesterol level (LDL cholesterol) is higher during the ingestion of fats comprised of saturated fatty acids than during the ingestion of polyunsaturated fats Fats such as olive oil made up of monounsaturated fats have little effect on cholesterol levels In general saturated fats are of animal origin such as those present in beef and pork meats and in dairy products that contain fats such as butter and cream Polyunsaturated fats are found in vegetable oils such as corn and safflower oils and in general the fats found in fish and fowl are more polyunsaturated than those of pork or beef While it is also generally true that foods rich in saturated fats contain more cholesterol saturation has an effect on cholesterol level independent of that due to cholesterol intake In most instances the cholesterol elevating effects of diet reflect the combination of an intake high in cholesterol as well as in saturated fat The sum of these effects is a variation of plasma cholesterol of 8% to 15% A decrease in total intake regardless of its composition that leads to weight loss produces an additional beneficial effect

HDL or high density lipoproteins HDL or alpha lipoproteins consist primarily of cholesterol and phospholipid and are composed of 50% protein In normal persons the HDL cholesterol is about one third of the total serum cholesterol and averages 55 mg /deciliter in women and 45 mg /deciliter in men Considerable evidence now indicates that in contrast to LDL the level of HDL relates in an inverse way to the risk of coronary artery disease Except for a well established increase in HDL with weight reduction the effect of diet on this type of lipoprotein remains uncertain Several reports suggest that increased intake [illegible] polyunsaturated fats lower HDL [illegible] as LDL cholesterol and a recent [illegible] investigation also found a positive rel[illegible] between cholesterol intake and HDL levels [illegible] findings require further confirmation and the magnitude of the potentially negative effects of diet if any is yet to be established

General considerations in the diet therapy of hyperlipidemia

1 Management aimed at altering elevat[ed] lipid concentrations should be a part of a gener[al] program for reduction of risk factors for cardi[o]vascular disease The two elements of this pro[]gram for which evidence is most secure are th[e] cessation or decrease in cigarette smoking and th[e] recognition and management of hypertensi[on] Several studies indicate that exercise will al[so] decrease the risk for cardiovascular events Th[e] use of diet or drugs to alter plasma lipids t[o] decrease the risk of vascular disease is a reaso[n]able component of therapy in patients with spe[]cial risk due to elevation in plasma lipids but th[e] efficacy of such therapy is less well establishe[d] than that for the other modalities discusse[d] above

2 Studies of the effect of diet on mortalit[y] have been disappointing but have been largel[y] limited to patients with or without heart disea[se] who are beyond the middle age These findings and the pathological evidence concerning th[e] time course of atherosclerotic disease sugge[st] that if diet is of value in prevention of this dise[ase] it will have to be instituted early in life There i[s] no real basis for the institution of diet therapy f[or] abnormal plasma lipids or in general for th[e] prevention of atherosclerosis in patients ol[der] than 65 years

3 Diet therapy should generally be determi[ned] by the nature of the pattern of abnormal i[n] plasma lipid concentration In evaluating [a] patient with hyperlipidemia total plasma chole[s]terol plasma triglyceride and HDL cholester[ol] should each be measured These values should b[e] obtained in patients who are following the[ir] normal patterns of activity and food intake a[nd] who have not recently suffered a serious illne[ss] such as a myocardial infarction Although th[e] cholesterol values are not altered immediately b[y] meals triglycerides are therefore plasma lipi[ds] should be determined at least 10 hours after th[e] last ingestion of fat

Although our understanding of hyperlipide[]mias is based on the concept of transport of li[pids] as lipoproteins lipoprotein eletrophoresis ran[] helpful in evaluation and treatment

Dietary factors and lipoproteins

It is now clear that an understanding of the relationship between plasma lipids the risk of vascular disease and attempts to alter this risk of diet requires consideration of these lipids as components of circulating lipoproteins There are four lipoproteins that occur in the plasma of normal persons and elevations in their levels reflects in almost all instances an increase in these lipoproteins rather than the presence of abnormal forms These lipoproteins are affected differently by dietary manipulations and have different statistical relationships to the risk for vascular disease In most instances with the exception of high density lipoproteins (HDL) measurement of cholesterol and triglyceride will suffice and the lipoprotein pattern can be predicted from those values making direct measurement of lipoproteins unnecessary

Chylomicrons Chylomicrons are lipoproteins made up almost entirely of triglyceride and they relate directly to fat ingestion in that they are produced by the intestine during fat absorption and do not appear normally in plasma except during the six to ten hours following fat intake Increase in plasma chylomicrons in the fasting state are not an important component of hyperlipidemias in man and in rare instances in which their concentration is increased they seem to have a weak association if any with increased risk for vascular disease For that reason they will not be discussed further except to make the general statement that they are reduced in plasma when fat intake is curtailed

VLDL or pre beta lipoproteins The lipoprotein other than chylomicrons that are rich in triglyceride is the VLDL or pre beta lipoprotein This lipoprotein is present at elevated levels in almost all adult patients with hypertriglyceridemia The amount of this lipoprotein in plasma has a direct relation to the risk of vascular disease It is increased in many patients with obesity particularly with high insulin concentrations and it is also seen at elevated levels in many diabetic patients of the insulin independent or maturity onset" type It has repeatedly been shown that weight reduction regardless of the composition of the diet results in most subjects in a decrease in plasma triglyceride (as VLDL) as well as in the accompanying hyperinsulinemia The long term effects of weight reduction with or without accompanying fall in plasma triglyceride upon the risk of developing cardiovascular disease remains unproven

In the patient with hypertriglyceridemia (elevated VLDL) who is not obese or in the patient who has achieved maximal weight loss but who remains hypertriglyceridemic the effect of diet is considerably less certain When normal persons or patients with hypertriglyceridemia are given a diet restricted in fat with a high carbohydrate content elevation in triglyceride occurs at least transiently Many authors believe that this response is temporary and that this diet coupled with cholesterol restriction and restriction of saturated fat is optimal therapy in patients with elevation of plasma triglyceride and in whom weight loss has been unsuccessful Other authors however have found that fat restricted high carbohydrate diets with total caloric content sufficient to maintain weight lead to increase in triglyceride concentration particularly postprandially In practice however this problem is rarely encountered since diet modified to restrict fat usually results in a decrease in total calories which in itself has a favorable effect on triglyceride concentration

Beta lipoproteins or LDL This lipoprotein consists mainly of cholesterol and most plasma cholesterol circulates in this form The well established direct association between plasma cholesterol concentration and the risk of vascular disease reflects variations in this lipoprotein Most of the variation in the plasma cholesterol within the normal population results from variations in the amount of this lipoprotein and in almost all instances elevations of cholesterol to abnormal levels in the absence of hypertriglyceridemia reflect increased levels of beta lipoprotein

It is now clear that in man alterations in cholesterol intake without other changes in diet affect its plasma level There is however uncertainty about the magnitude of this effect and the level of cholesterol intake beyond which such an affect can no longer be seen The average intake of cholesterol in the United States is 500 to 600 mg per day and it seems likely that increases beyond that range may have a small impact if any on the plasma level [2] In fact the major effect of dietary cholesterol seems to be demonstrable only when cholesterol intake is in the range of 300 mg per day and below and at that range restrictions in intake seem to produce decreases in plasma levels of about 10% to 15% It

Annotations

The importance of the history in the medical clinic and the cost of unnecessary tests

The use of routine investigations in the medical outpatient department is widespread The experienced doctor however realizes the limited value of such investigations and the importance of the clinical history and less so of the clinical examination in the diagnosis and management of patients To try to measure the usefulness of the three basic clinical methods—history examination and investigation—a two year study of medical outpatients was undertaken in a typical district general hospital serving a largely urban population of 225 000 people

All new patients referred by a family physician to a general medical clinic with a cardiological bias were included in the study The new patient was examined at his first attendance by the medical registrar or senior house officer who took a detailed history Routine investigations in all patients comprised hemoglobin white cell count erythrocyte sedimentation rate blood urea serum electrolytes and blood sugar estimations chest radiograph and electrocardiogram In addition any appropriate special investigations were also arranged such as exercise tests, barium studies, electroencephalography etc After a short interval the patient returned to the clinic to see me when the following steps were undertaken

1 The referral letter was read carefully and a note was made on whether a specific diagnosis was offered or whether referral was on the basis of symptoms/signs only

2 The history obtained at the first attendance was read and supplemented by any relevant questions that had been omitted by the junior staff

3 A specific diagnosis was made where possible and the management was decided on the basis of this completed history Management could be referral back to the family physician with or without treatment follow up in the medical clinic again with or without treatment, hospital admission or referral to another hospital department.

4 The initial examination findings were studied and any omissions again were made good by me

5 The diagnosis and management based on the history were reviewed in the light of the examination findings and any necessary modifications were made

6 Finally the investigations were assessed and any contribution by routine investigation or special investigation to diagnosis and management was assessed

To check the accura y of the hospital diagnosis a questionnaire wa circulated t famil physicians 18 to 30 months after the initial ref rral a kin whether the diagnosis was still considered correct or wheth r an ne developments had occurred to alter the hospita diagrosis. Th questionnaire was not however sent in relation to all patients seen Where the hospital diagnosi confirmed the ph ician s diagnosis—for instance in anginal patients—or where objective findings placed the dia nosi beyond doul t a in hyperten ion rheumatic heart disease diabetes thyrotoxicosis, etc no fol was considered necessary

In the two year period 630 outpatients were seen. The ro of the history examination and investigations in diagnosis is shown in Table I The history decided diagnoses in two thirds of the cardiovascular pa clinical examination contributed to only one-quarter of noses

When the 180 patients with chest pain are separately the history gave the diagnosis in 90% and nation was of no diagnostic value at all. Routine inves- tions mainly chest radiographs and electrocardiogr helped with only 3% of diagnosis and special tests, exercise electrocardiography helped with 6% T value of the history was also high in neurological with examination contributing even less than i lar problems and routine investigations were agair value

The history was also the main diagnostic method ratory urinary and miscellaneous problems. It was of value in alimentary problems, where the main diagnostic was provided by the special radiological tests. Special inve- gations were also of primary diagnostic value in en problems Clinical examination and routine were of no help in alimentary problems and little urinary problems

The importance of the history examination and tions in deciding management is shown in Table II history was the major determining factor in the lar neurological respiratory and miscellaneous Examination was most helpful in respiratory disease in diagnosing chronic bronchitis and emphysema, and less so in cardiovascular problems, where the main were hypertension and rheumatic heart disease Examina helped least in alimentary problems. Routine inves were of least value in cardiovascular and neurological agement and of most value in endocrine problems, mainly to blood sugar concentrations in diabetic pa also the routine chest radiograph was important in management of respiratory problems, and routine urine exa ination was helpful in urinary problems. The special in gations were again of most value in alimentary and problems

The incidence of abnormal results in all the routine gations is shown in Table III which also indicates whether t abnormality relates to the primary condition for which t patient was referred or to an associated unexpected clinically significant condition The limited number of po results with every investigation in every group of pa obvious. The over all incidence of positive blood or results did not exceed 5% and when considered in rela the primary condition for which the patient was referred.

4 In patients with hypertriglyceridemia with or without moderate elevations of cholesterol the most important diet therapy is weight loss The patient should be made aware that the basis for a weight reduction program has specific therapeutic implications and that even moderate degrees of weight loss may be associated with decrease of plasma triglycerides towards normal levels even if optimal weight is not achieved

5 In patients with hypercholesterolemia in the absence of hypertriglyceridemia the diet should include the three elements of diet known to lead to cholesterol reduction—restriction of saturated fat provision of at least 10% of fat calories as polyunsaturated fats as well as a decrease in cholesterol intake In general terms this is a diet that restricts egg intake the ingestion of beef and pork products (including fat containing dairy products) and requires the addition of unsaturated fats in the form of vegetable oils and soft margarines In addition to eggs organ meats *such as liver kidney are also very* high in cholesterol content The most favorable sources of protein are fish and fowl In general shell fish such as lobsters and shrimp contain as much cholesterol per gram of protein as do beef and pork products The value of total fat restriction in a cholesterol lowering diet is not fully established Since there are marked individual variations in the response to this type of diet it is important to measure the effectiveness of the diet program after approximately four weeks of treatment In patients with serious elevations of their cholesterol concentrations in whom such therapy is ineffective therapy with drugs should be instituted.

6 Alcohol ingestion has a complex relationship to plasma lipid and development of atherosclerosis. In general *high levels of alcohol ingestion* seem to be associated with increase in VLDL triglyceride particularly in persons whose levels are already elevated There is little if any effect on LDL, but an increase in HDL cholesterol has been shown Thus alcohol could be advantageous or disadvantageous although most studies show that when ingested at more than moderate rates alcohol is associated with increases in mortality rates. The relationships between alcohol and coronary heart disease and its individual risk factors are discussed in a recent review

Alimentary	52	14	173 32
Respiratory	36	25	309 50
Urinary	19	12	148 56
Miscellaneous	63	34	420 92
Total cost in the two year study			£ 5 645 28
Cost per year			£ 2 822 64

In the follow up questionnaire to the family physician on the original hospital diagnosis in 548 patients there was a 60% response and the overwhelming majority of the answers confirmed the original diagnosis.

The cost of the routine investigations in those patients already diagnosed on the basis of the history and the examination is shown in Table IV The annual cost in the Medical Clinic was £2,823 (approx $6,500 U.S) A small survey among 28 physicians in the Trent Region to discover how many carried out routine investigations in their new outpatients similar to the procedure in the present study showed that 43[illegible] did so If this pattern was reflected nationally among the 1 044 hospital physicians employed in the N H S the total annual cost to the N H S of these useless investigations would be £ 1 26[illegible] 083 (almost 3 million dollars U S)

The study has clearly shown the major importance of the history in deciding the diagnosis and management of 630 medical outpatients. These findings support the views expressed by Platt on the vital importance of the history in clinical medicine Similar findings were also reported by Hampton and associates in a more limited study of 120 medical outpatients Clinical examination contributed much less diagnostic help its main benefits being confined to cardiovascular problems in the detection of hypertension and valvular heart disease and in respiratory problems in indicating chronic bronchitis and emphysema Similar results emerged in relation to the major value of the history in patient management with much less help provided by examination findings.

Routine blood count erythrocyte sedimentation rate blood urea and serum electrolyte estimations were of primary diagnostic help in only 1 [illegible] of patients [illegible] ver all Routine urine examination and blood sugar estimations also contributed little to diagnosis apart from [illegible] patients Chest radiographs were slightly more help[illegible] atory and cardiovascular problem [illegible] was th[illegible] gram in cardiovascular problems. N vert[illegible] nd blood sugar estimations in diabe[illegible] radiographs and electrocardiograms in respiratory and cardiovascular problems are hardly "routine" since they are specifically orientated to these problems.

The special investigations were of more value in diagnosis and management. The most useful were barium meals and cholecystograms, which decided most of the alimentary diagnostic problems. Thyroid function tests and glucose tolerance tests were also of considerable help in the appropriate endocrine disorder The exercise electrocardiogram contributed little in cardiovascular problems and the electroencephalogram was also of minor value in neurological problems.

What are the implications of the present study? First and foremost is guidance on the educational requirements of medical students Conventional training is based on a combination of history and examination findings before the diagnosis is considered A similar system is widespread in published case presentations in medical journals Much greater emphasis should be placed on the diagnostic and management value of the history Students and postgraduates should be well trained in taking a good history and in drawing diagnostic conclusions from the history before embarking on the examination This will encourage the student to seek specific examination findings to confirm or refute the diagnosis based on the history The traditional case presentation of history and examination followed by differential diagnosis should be changed to history differential diagnosis, and relevant examination findings A similar approach could be encouraged in medical journals and textbooks where inadequate emphasis on the importance of the history is often all too evident.

The study has also shown clearly the limited value of routine blood investigations Some doctors may carry out these routine investigations because they think it makes their approach more scientific others, perhaps, because they fear they might miss some other serious coexistent condition yet others may consider it desirable to have baseline measurements of these parameters to compare with possible future disorders Emphasis on the scientific investigational approach, however commendable though this may appear could lead to unselective application of laboratory investigations and minimize the importance of good history taking in diagnosis and management The value of the routine blood and urine investigations in the present study in showing unsuspected significant coexisting disease was small only 9.5[illegible] of patients. A similar limited incidence of unexpected abnormal routine laboratory results was also reported by Bredd in his study of 200 medical outpatients

Another important consideration is the cost of unnecessary routine investigations. In the Barnsley District General Hospital alone an annual saving of £2,823 ($6,500) could have been achieved in one medical clinic by omitting routine investigations in patients in whom the diagnosis had already been made on the basis of the history and clinical examination, and if the national picture followed the pattern of the local survey carried out in the Trent Region an annual total of over £1[illegible] million could have been saved

The justification for any investigation should surely be to answer a specific clinical question relating to diagnosis and management only when there is doubt as to either or to measure the effect of treatment that cannot be assessed on symptoms or signs alone Where these requirements are not operative however and where the result of the in[illegible]

* Primary condition for which patient was referred.
† Unexpected co-existent but clinically significant condition.

[illegible] diagnostic help in even less. The most useful routine tests were the chest radiograph and electrocardiogram but even they were of primary diagnostic help in only 5% and 12% respectively.

The diagnostic value of the more specific special investigations was greater. A positive test occurred most often with the [illegible]ogram in respiratory problems, but even then it decided the diagnosis in only [illegible]%. The glucose tolerance test was of the greatest diagnostic value of all the special tests, diagnosing [illegible]0% of the diabetic problems. Barium meal tests and cholecystography contributed substantially to the diagnosis of alimentary problems. The electroencephalogram, though often positive, decided the diagnosis in only 16% of cases; echoencephalogram and brain scan were of no value. Thyroid function tests were of considerable diagnostic value. [illegible] exercise test was of negligible diagnostic help in chest pain.

Table I Conditions where ASH is reported to occur

Condition	*No of cases/ Total cases*	*% of cases*
Acromegaly	8/9	88
Malignant hypertension	14/30	46
Chronic renal failure	7/23	30
Systemic hypertension	12/40	30
Systemic hypertension	3/30	10
Systemic hypertension	9/234	4
Mitral valve prolapse	16/190	8
Aortic valve disease	5/59	8 5
Mitral valve disease	2/36	5 5
Aortic & mitral valve disease	3/37	8 1
Coronary artery disease	4/79	5
Miscellaneous cardiac diseases	8/100	8
Miscellaneous cardiac diseases	40/100	40
Aortic stenosis & bicuspid valves	5	—
Weight lifters	14/14	100
Athletes	4/10	40
Normal subjects	5/10	50

In ludes patients with posterior infarction and congenital heart disease

show patients in whom the septum and posterior wall are of equal thickness There are only four echocardiograms which claim to show ASH and the interpretation of some of these is questionable While we do not deny that ASH can occasionally occur in conditions other than IHSS it is in our experience an infrequent finding Therefore rather than report our own experience (which might be open to dispute) we reviewed the left ventricular echocardiograms published in widely available echocardiographic textbooks and in current cardiology journals These contained numerous high quality echocardiograms from patients with those conditions listed in the table in which the thickness of the septum and posterior wall could be confidently measured We found no examples of ASH but on the contrary in all cases the thickness of the septum and posterior left ventricular wall were found to be remarkably similar

There are several technical problems and pitfalls in the correct identification of right and left ventricular endocardial surfaces This is essential for the measurement of septal and posterior wall thickness and relatively small errors can lead to an incorrect diagnosis of ASH For example it is easy to confuse [illegible] tricuspid valve chordae or papillary [illegible] right ventricular septal endocardium [illegible] thickness Over estimation of septal thickness [illegible] incorrect angulation of the [illegible] by beam width artefact [illegible] recent surveys has shown [illegible] others 20 measure septal thickness [illegible] mitral observer error [illegible]

In view of the [illegible] septal and posterior wall [illegible] published echocardiograms [illegible] conditions other than IHSS [illegible] ASH in [illegible] right ventricular hypertrophy the question arises as to whether some of the cases of ASH in these reports are erroneous The sceptical reader may be justified in not accepting a significant association between ASH and the conditions listed in the table until he is able to measure for himself in such reports echocardiograms clearly demonstrating ASH Because space in any publication is limited composite illustrations containing echocardiograms from several patients with no more than one cardiac cycle from each could be provided

Of saphenous vein arteriosclerosis

The saphenous vein *in situ* never develops art rios rotic changes. It can develop phlebosclerosis if there are varicose veins or an arteriovenous shunt in the area. But, if a segment of the vein is used for coronary artery bypass surgery t develops arteriosclerosis.[1] Why there and not in the leg? It must be due to the intraluminal pressure of the venous segment when it is used for the aorta-coronary shun and the trauma to the venous segment associated with its isolation and transplantation. The exposure to tobacco diet blood substances etc., is the same and is present for all veins as well as for all arteries As pointed out previously intra arterial pressure and now high intravenous pressure in the venous segment, is an important factor in the production of arteriosclerosis. Arteriosclerosis can be due in part to the anatomic and other disturbances associated with the system related to removal and transplantation of the venous segment. The areas of trauma can provide the nidus for the "arteriosclero sis to develop. The beating heart and the chroni adhesive pericarditis associated with venous aorta-coronary bypass must produce further physical trauma to the saphenous ven us segmen as the heart moves abou during each heart beat This could be an additional factor which contributes etiologically to the production of arteriosclerosis in the venous segment A s udy of such a venous bypass segment could contribute to understanding the pathogenesis of arteriosclerosis.

Asymmetric septal hypertrophy in conditions other than IHSS

Since asymmetric septal hypertrophy (ASH) was first demonstrated by echocardiography in patients with idiopathic subaortic stenosis (IHSS) and in some of their first-degree relatives it has been reported in many other conditions These conditions can be divided into two groups. First, there are those disorders where the interventricular septum might be expected to be thicker than the posterior left ventricular wall—i.e., inferior myocardial infarction and right ventricular hypertrophy—whether due to primary pulmonary h perten sion or to congenital heart disease Secondly there are a large number of conditions where the presence of ASH could not be anticipated (Table I) It is the purpose of this Annotation to draw a tention to the contrast between on the one hand, the plethora of reports of ASH in this latter group and, on the other the paucity of published echocardiograms supporting them.

Only some of the publications l ed in the table are illustrated by echocardiograms, and curiou y most of these

neurons involved The consequence will be overeating Many obese people are compulsive eaters and their cravings for food are often uncontrollable Their condition has been described as carbohydrate addiction We think that the resemblances to narcotic addiction support our proposal of a common opioid mechanism Considering the unpleasant mental symptoms during withdrawal from morphine addiction it would be surprising if there were not some psychological symptoms associated with autoaddiction

Eating between meals

Enkephalin differs from morphine in its short half life less than a minute so as soon as the food leaves the duodenum there will be a rapid disappearance of enkephalin from the environs of the receptor neuron This contrasts with the relatively slow removal of morphine from the circulation This disappearance of enkephalin about a couple of hours after a meal will cause excessive activity in dependent neurons and will constitute a withdrawal syndrome before the next meal is due Eating snacks between meals will abate the consequent cravings for food and of course eating between meals is a common feature in obesity

Sugar

It is a general observation that sugar has a special relationship to appetite and to satiety We can for example eat a sweet when we are already replete with the savoury meat and vegetable course Sugar must have been a rare item in the diet of preagricultural man and the evolution of the satiety system must have taken place with a relatively sugar free duodenum In the intracellular digestive assay for the estimation of calorific value the direct diffusion of sugars into the cell might well swamp the process With an average daily consumption of about 130 g of sugar the sweet products of modern food technology may result in many people today being unable naturally and unconsciously to regulate their food intake

In conclusion if we are not all to be in a perpetual state of addiction the maximum enkephalin released by the sensory cells must not regularly exceed the amount required to ... the activity of the receptor neurons While the system ... cope with episodic excess chronic excess of enkephalin ... be pathological, and even a small regular excess would lead ... some degree of autoaddiction

Autoaddiction a hypothesis on hunger and obesity

During the past ten years a group of some seven peptides with putative neurotransmitter and hormonal function have been found both in the brain and the gut One of these enkephalin has aroused special interest because it occupies the same receptor sites as morphine Experiments in the brain have shown that neuronal pathways, already firmly associated with the reduction of hunger drive are most probably part of an enkephalinergic system. Our proposal links this work with the enkephalin-containing cells in the gut to constitute a system which responds to the appropriate amount of food in the stomach by switching off eating It gives the sensation of satiety and the feeling of postprandial well being and leepiness. From a consideration of the opioid nature of the system we arrive at a feasible dysfunction by which a person can become addicted to his endogenous opiates a condition which we have called "autoaddiction "

Satiety

Experimental work has shown that satiety and cessation of feeding are elicited by samples of food from the stomach activating receptors in the wall of the duodenum We propose that enkephalin is a mediator In the gut enkephalin is found in the highest concentration in the antrum of the stomach and the duodenum, both in neurons and in open-ended secretory cells The enkephalin containing cell is probably a receptor secretory cell, sampling the contents of the duodenum at the open end of the cell and releasing enkephalin as a local hormone at the other We propose that the released enkephalin inhibits nearby afferent enkephalinergic neurons to switch off feeding and the hunger drive in the brain The strength of the reward depends on the number of secretory cells recruited by the influx of food into the duodenum The secretion of enkephalin from each can do no more than inhibit the activity of the neuron

Addiction

All the indications are that endogenous opiates are at least as addictive as morphine and we can see no good reason why the release of excess enkephalin should not be as addictive as circulating morphine We assume that addiction involves cellular changes as in the theory proposed by Collier in which opiates act by inhibiting the production of cyclic AMP and hence the activity of the neuron Continued inhibition leads to an increase in the capacity of the neuron to make more cyclic AMP and so it will need more opiate to suppress it (tolerance) The removal of the excess opiate unleashes the increased capacity to increase cyclic AMP and the resulting hyperactivity of the neuron is the cellular equivalent of the withdrawal syndrome

Autoaddiction and obesity

If for example the receptor-secretory cells in the duodenum overproduce and release too much enkephalin (or if the released enkephalin is not degraded with sufficient rapidity) then the regular excess of enkephalin over and above the amount required to reduce the activity of the receptor neuron will have the same effect as circulating morphine Repeated regularly after meals the excess enkephalin like uniform doses of morphine will soon cease to satisfy Tolerance/dependence will develop Some neurons cannot now be switched off by the released enkephalin and the satiety mechanism fails to an extent, depending on the numl

ity may be responsible[2] recent reports have indicated the possible causative role of the renin angiotensin system in the generation of the increased peripheral vascular resistance

Increased levels of plasma renin and plasma renin activity have been reported during conventional CPB Increase in the plasma level of angiotensin I has also been reported In a previous study the author and his colleagues have demonstrated a marked rise in plasma angiotensin II (AII) levels during nonpulsatile CPB with persistence of these elevated levels for around two to four hours postoperatively These elevated levels of plasma AII are significantly greater than those found during or after major non bypass procedures Elevation in the plasma level of angiotensin II during and after the period of CPB might therefore be considered likely to be of significance in the development of increased levels of peripheral vascular resistance

In view of this possible association between increased plasma AII levels and increase in vascular resistance 12 consecutive patients who had submitted to elective open heart surgical procedures were studied Six patients had prosthetic valve replacement procedures and six had coronary artery bypass grafting The mean age of the patients was 52 years There were seven males and five females Conventional nonpulsatile CPB was used in all cases with a bubble oxygenator The pump flow was calculated according to the standard formula

$$\text{Flow} = 2\,4\ \text{L/m} \quad \text{min}$$

The mean total bypass time was 92 3 minutes the mean temperature during perfusion was 35.5 C and the mean packed cell volume during bypass was 25%

In each patient blood samples for plasma angiotensin II estimations were obtained on full pump flow at the onset of total CPB and on full pump flow at the end of total CPB At these times measurements were obtained allowing the calculation of peripheral vascular resistance index Peripheral vascular resistance index (PVRI) was calculated according to the formula

$$\text{PVRI} = \frac{\text{mean arterial blood pressure} - \text{CVP}}{\text{cardiac index}}$$

Plasma angiotensin II levels were measured by the standard radioimmunoassay method In each of the 12 patients studied PVRI rose during CPB from a mean level of 20 87 ± 1.21 SEM to an end CPB level of 27.83 ± 1 61 SEM The mean rise in PVRI during bypass was 6 96 index units In percentage terms this is an increase in vascular resistance of 33.35% Similarly plasma angiotensin II levels rose during bypass from a mean level of 78 pg/ml ± 1 6 SEM to a mean end bypass level of 231 pg/ml ± 778 SEM (normal plasma AII level = < 35 pg/ml) The rise in plasma angiotensin II levels was correlated with the rise in peripheral vascular resistance index levels for each of the 12 patients The correlation coefficient obtained (r) was 0 91 This indicates a highly significant correlation between the quantitative change in plasma angiotensin II levels and the quantitative rise in peripheral vascular resistance index ($p < 0\,001$)

This study lends support to the concept that activation of the renin angiotensin system during conventional nonpulsatile CPB with the consequent elevation in the plasma level of angiotensin II may be a significant factor in the development of increased vasoconstriction during and after open heart surgical procedures If this is indeed so there are important therapeutic considerations regarding the management of the vasoconstriction It is increasingly recognized that reduction in elevated levels of vascular resistance is beneficial in the majority of patients in the early period after open heart surgery Several authors have recently demonstrated significant improvement in hemodynamic status in patients after open heart surgery who received vasodilator therapy for example with nitroprusside This benefit was considered to reflect improvement in left ventricular performance If angiotensin II is of major etiological significance in post-bypass vasoconstriction specific therapy designed to counteract the vasoconstrictive effect of angiotensin II would offer at least theoretical advantages over nonspecific vasodilator therapy particularly in relation to the known physiological effect of angiotensin II in producing increased subendocardial ischemia Specific anti AII therapy therefore offers a possible therapeutic superiority over current therapies (e g nitroprusside) in blocking the coronary vasoconstrictor effect of angiotensin II in addition to reducing elevated vascular resistance levels

In this regard recent reports using angiotensin converting enzyme inhibitor substance have suggested that such theoretical advantages of specific anti AII therapy may in fact be evident in clinical practice If however we continue to hold the maxim that prevention is better than cure attention ought also to be directed towards the prevention of the excessive activation of the renin angiotension system by modifying cardiopulmonary bypass perfusion The use of pulsatile flow during CPB is widely reported in the literature to be associated with significantly lower levels of vascular resistance compared to conventional nonpulsatile perfusion It may be that this hemodynamic effect of pulsatile CPB is achieved by means of reduced activation of the renin angiotensin system producing significantly lower levels of angiotensin II during the period of perfusion and in the early post bypass period

The role of angiotensin II in the development of peripheral vasoconstriction during open-heart surgery*

Increased peripheral vasoconstriction is more commonly recognized during and after open heart surgical procedures using conventional techniques of cardiopulmonary bypass (CPB) Peripheral vascular resistance ing the period of perfusion and of the postoperative period Initial clinical characteristics of this synd no clear understanding of the While some reports have sugges

*This work was c rried ut with th d of gr t from the British Heart Foundation

neat and to lie with the hairline Cerebral blood flow and oxygen utilization increased The first patient of the series had a striking improvement in power Before the operation his right arm had been totally paralyzed for six weeks and within ten days of the procedure movement appeared first at the shoulder then at the elbow and finally at the wrist At the end of six weeks his arm movements were completely normal Three months later his inaccessibly stenosed internal carotid artery occluded and he suffered a recurrent completed stroke His deficit on this occasion was severe but the arm was relatively spared Most patients had a reduction in tone with improvement in power enabling an improvement in gait and stability

Psychological assessments were performed before and after operation in seven of the nine patients Improvement was claimed in six out of seven The left sided bypasses produced a striking improvement in verbal tests and intellectual improvement of one sort or another was demonstrable in all but one patient

The preliminary results suggest that extracranial to intracranial bypass may produce an improvement in some patients with longstanding moderate completed ischemic stroke As some of the patients in the report had a long standing total paralysis of the arm before surgery these deficits may have been regarded as too severe to fall within the criteria for entry into the Canadian cooperative study

Extracranial to intracranial microrevascularization for the treatment of completed ischemic stroke

Extracranial surgery for internal carotid artery occlusion has had poor results, and attention has turned recently towards the possible improvement of cerebral blood flow by intracranial procedures Jacobson and Suarez first used the operating microscope for anastomosing small vessel and Donaghy reported seven human middle cerebral artery embolectomies using a T tube Yasargil and Donaghy then performed the first successful extracranial to intracranial bypass in man The end of the superficial temporal artery was anastomosed to the side of a cortical branch of the middle cerebral artery

There has been a recent interest in the British press following leading articles in the *British Medical Journal* and in the *Lancet* and a report of results of this procedure for the treatment of completed ischemic stroke

Extracranial to intracranial microrevascularization has been performed mainly for transient ischemic attacks prolonged reversible neurological deficit progressing stroke and much less commonly for completed stroke In Great Britain the procedure has not gained much popularity until recently The feeling among many clinicians there has been that most patients considered for the procedure were far too well to merit angiography and bypass surgery The procedure has recently become more popular and there has been less opposition to it for patients with completed ischemic stroke for whom nothing else could be offered

In the recent report completed strokes occurred between 1½ and 12 months (mean six months) before surgery The main deficits were weakness of the arm dysphasia intellectual deficit and to a lesser extent reduction in power in the leg All patients were alert and had some evidence of retained function in the affected hemisphere All patients had low density areas comparable with cerebral infarction on computerized axial tomography The deficits were stable at the time of surgery and were thought unlikely to show further spontaneous improvement A power record of the affected muscles an assessment of the speech deficit and regional cerebral blood flow estimations were performed and were repeated after the operation Psychological assessment was carried out before and after operation the tests were of intelligence verbal fluency (in the left sided cases) visual perception (in the right sided cases) and memory for both visual and verbal material

The operation was performed by a vascular surgeon with experience in microvascular surgery with the assistance of a neurosurgeon Using the operating microscope the end of the superficial temporal artery was anastomosed to the side of an appropriate cortical branch of the middle cerebral artery using interrupted 10/0 sutures

All nine of the anastomoses remained patent as assessed by arteriography or directional Doppler probe with a patent anastomosis it is possible to feel the pulsation of the superficial temporal artery All patients were alive and well at the time of writing and the procedure had an insignificant morbidity there was no skin flap sloughing and the scar proved to be

Letters to the Editor

Mitral prosthetic dehiscence and paraprosthetic regurgitation

To the Editor

In consequence of the case report by Chun and co workers concerning the Bjork Shiley mitral valvular dehiscence we would like to refer to our report of five patients with a Bjork Shiley mitral valve prosthesis and paraprosthetic regurgitation confirmed by cardiac catheterization left ventricular cineangiography and reoperation In four of these patients an abnormal anterior movement of the disc and the whole prosthesis, similar to that which Chun and associates described was found at the beginning of diastole in the echocardiogram. Other echocardiographic findings were an increased left atrial diameter compared with preoperative or previous postoperative measurement increased left ventricular end diastolic and stroke volumes and normal systolic posterior motion of the interventricular septum with a wide amplitude In two of these patients no murmurs were audible so that the paraprosthetic leakage may be insidious as previously described, and difficult to diagnose noninvasively without echocardiography In cardiac catheterization large v waves in the pulmonary capillary wedge tracings 30 to 60 mm Hg gradients across the mitral valve at the beginning of diastole and 20% to 50% mitral regurgitation fractions measured from quantitative left ventricular cineangiography were found in these patients Also the time from the aortic valve closure sound to the opening sound of the mitral prosthesis (A_2 MVO interval) in the phonocardiogram was abnormally shortened (60 ± 10 msec) suggesting increased left atrial pressure

Four patients were reoperated upon and in three of them the movement of the prosthesis in the echocardiogram was found to be normal after reoperation Left atrial diameter left ventricular end-diastolic and stroke volumes as well as the septal amplitude also decreased after successful reoperation In one patient in whose echocardiogram the movement of the prosthesis remained abnormal after reoperation a slight residual paraprosthetic leakage was found in a later catheterization study

Lately we have seen one more patient with paraprosthetic leakage confirmed by reoperation Abnormal movement of the prosthesis in the echocardiogram was found and we have never seen an abnormal prosthetic movement like this without paraprosthetic leakage The appearance and magnitude of this abnormal anterior movement of the prosthesis in the echocardiogram seems to depend on the position and magnitude of the detachment of the prosthesis from the mitral anulus as well as on the pressure gradient across the mitral valve at the beginning of diastole Because echocardiographic measurements in patients with normal prosthetic function did not change significantly after the first post perative month we recommend the initial postoperati e h cardiographic examination to take pla e up t the er d f the f rst postoperative month in every patient with a mitral al e prosthesis as a reference for later studies

causalgia are found within the same left dermatomes. The heart apparently is located within these dermatomes These clinical manifestations conform with studies in experimental animals and man which show the role of the left stellate sympathetic ganglion and the other sympathetic ganglia of the left side of the neck and upper thoracic region in neural regulation of cardiac function The mechanism for neurologic disturbances and location of the resultant manifestations needs careful study It is interesting though that the distribution of the clinical manifestations of cardiac causalgia within the body is limited to certain left dermatomes. This distribution is thought provoking. It is tempting to conjecture the possible clinical beneficial effects for patients with cardiac causalgia that might be expected from procaine blocking or resection of left stellate sympathetic and upper thoracic sympathetic ganglia

type of cardiac arrhythmia for a brief period She then remained well until the age of 21 years (1979) when she died suddenly unrelated to exertion In neither case was there a family history of sudden death or heart disease but no clinical investigations were made of the other family members

Although these two cases may simply identify me as an extremely rare" cardiologist who has encountered sudden death in multiple patients with mitral valve prolapse I think the authors might well have downgraded their rating of sudden death prospects in this syndrome from "extremely rare" to "rare" or "uncommon Perhaps the auscultatory findings of mitral valve prolapse carry a less favorable prognosis when heard in childhood than when initially heard in the adult years.

We thank Dr Anderson for his interesting letter suggesting that mitral valve prolapse might carry a less favorable prognosis in childhood We suppose that this is a possibility The incidence of mitral valve prolapse increases greatly with age suggesting a "wear and tear" effect superimposed on a minor congenital abnormality of the cusp and chordal tissue Maybe the valve abnormalities have to be more extreme to cause prolapse in children On the other hand sudden death, presumably from dysrhythmia would be unlikely in the absence of myocardial disease or a prolonged QT interval. One of Dr Anderson s patients did indeed have an abnormal electrocardiogram but there is no note of the QT interval. Dr Anderson does not tell us about the necropsy findings.

On rheumatic fever in children

To the Editor

I have read with interest the excellent review of Rheumatic fever in children by Disciascio and Taranta and congratulate the authors on their magnificent work The subject and its geographic importance are well covered The following comments, however are in order

The disease continues to be a [illegible] f morbidity and mortality in the "deve [illegible] ntries [illegible] world Among the factors affecting the higher incidence of the disease [illegible] these areas the most important in my opinion are th[illegible] unfavorable socioeconomic conditions. One would thus [illegible] to look at the whole spectrum of these conditions. Obvious[illegible] crowding in houses is a contributing factor so is the unava[illegible] ability of proper medical care etc But one often neglecte[illegible] aspect of the spectrum is nutrition Although there is [illegible] evidence of a predisposing dietary deficiency in adult life th[illegible] role of nutrition in the first six months of life in regard t[illegible] rheumatic fever has not yet been thoroughly investigated. I[illegible] my opinion there are some clues as to the possible role o[illegible] nutrition in the first year of life in rendering a pers[illegible] susceptible to rheumatic fever It has been shown tha[illegible] infantile malnutrition in the first six months of life leads to [illegible] imbalance of the immune system—i e B and T cell fa[illegible] and complement production Since autoimmune disea[illegible] are felt to result from such imbalances and rheumatic fever i[illegible] favored by many as an autoimmune disease one can [illegible] relate the two together and at least suggest that in th[illegible] economically deprived populations where infantile mal[illegible] tion is quite common genetically susceptible individuals cou[illegible] be hypersensitized by immune imbalance and thus become a[illegible] oversusceptible host Future exposure to rheumato[illegible] streptococci in such individuals would result in an attack o[illegible] rheumatic fever The possibility that some serotypes of strep[illegible] tococci in areas of high incidence are more rheumatogenic [illegible] suggested by a 57% M typability in 100 strains of group [illegible] beta hemolytic streptococci studies in an area of high inc[illegible] dence The observation that the disease is rather rare [illegible] the Egyptian countryside as opposed to Cairo where [illegible] population live under conditions of extreme crowd[illegible] similar to our observations in Iran We noted that over [illegible] patients suffering from severe rheumatic heart disease we[illegible] from urban and heavily populated areas and the majority ha[illegible] been born in these areas Thus, the exposure of immigra[illegible] unfamiliar serotypes is probably not always the case Ra[illegible] one would have to examine the factors created by crowd[illegible] such urban and overpopulated areas some of which probab[illegible] play a role in the pathogenesis of the disease Neverthele[illegible] is known that infantile malnutrition is more common in [illegible] communities than in rural areas where traditionally brea[illegible] feeding has continued to be practiced Thus studies of th[illegible] relation of nutrition in the first six months of life in makin[illegible] host more susceptible to environmentally triggered au[illegible] mune disease can open an avenue to the pathogenesis [illegible] rheumatic fever

Our experience with over 1 000 children with rheuma[illegible] heart disease showed that mitral stenosis was the second m[illegible] common cause of isolated rheumatic valvular le[illegible] accounting for more than 20% of the cases. In our series [illegible] have clearly distinguished between pure mitral s[illegible] those stenoses associated with mitral regurgitation All [illegible] children with severe mitral stenosis who underwent s[illegible] were felt to have rheumatic valves (either duri[illegible] surgery or [illegible] subsequent pathologic examination of the valves) a[illegible] about 60% a history of rheumatic fever was elicited. In [illegible] instance did the valve have the characteristics of conge[illegible] mitral stenosis If one strongly argues a viral etiolo[illegible] mitral stenosis If one strongly argues a viral etiology f[illegible] disease as previously suggested it will have to be a be[illegible] hemolytic sterptococcus-dependent virus otherwise [illegible] cases would have been observed elsewhere in the world

As suggested by the authors, the Jones [illegible] boundaries between disease and nondisease states. As p[illegible]

Idiopathic mitral valve prolapse and sudden death

To the Editor

In their review of mild mitral regurgitation and its most common cause mitral valve prolapse Leatham and Brigden conclude that sudden death is extremely rare Unfortunately this has not been my experience inasmuch as I have encountered two sudden deaths among the approximately 50 children in whom I have made a diagnosis of idiopathic mitral valve prolapse One was a girl whom I first examined at nine years of age eight months after her family physician had first heard a heart murmur on a routine examination Aside from the late systolic murmur and click the only finding of note on interval examinations over the years was a flattening or inversion of the T waves in Leads 2 and 3 She had no symptoms until the age of 21 years (1974) when she developed palpitations, confirmed as ventricular premature beats by electrocardiography Several days later and before any therapy had been started she died suddenly unrelated to exertion The second case was a girl who had a typical late systolic murmur and click when I first examined her at seven years of age two years after her family physician had noted an abnormal heart sound Her electrocardiogram remained normal over the years but at 19 years of age she had some
